Abstract

Kleene algebra with tests (KAT) is a decidable equational system for program verification, that uses both Kleene and Boolean algebras. In spite of KAT’s elegance and success in providing theoretical solutions for several problems, not many efforts have been made towards obtaining tractable decision procedures that could be used in practical software verification tools. The main drawback of the existing methods relies on the explicit use of all possible assignments to boolean variables. Recently, Silva introduced an automata model that extends Glushkov’s construction for regular expressions. Broda et al. extended also Mirkin’s equation automata to KAT expressions and studied the state complexity of both algorithms. Contrary to other automata constructions from KAT expressions, these two constructions enjoy the same descriptional complexity behaviour as their counterparts for regular expressions, both in the worst case as well as in the average case. In this paper, we generalize, for these automata, the classical methods of subset construction for nondeterministic finite automata, and the Hopcroft and Karp algorithm for testing deterministic finite automata equivalence. As a result, we obtain a decision procedure for KAT equivalence where the extra burden of dealing with boolean expressions avoids the explicit use of all possible assignments to the boolean variables. Finally, we specialize the decision procedure for testing KAT expressions equivalence without explicitly constructing the automata, by introducing a new notion of derivative and a new method of constructing the equation automaton.

Keywords: Kleene algebra with tests, automata, equivalence, derivative.

1 Introduction

Kleene algebra with tests (KAT) [11] is an equational system that extends Kleene algebra (KA), the algebra of regular expressions, and that is specially suited to capture and verify properties of simple imperative programs. In particular, it subsumes the propositional Hoare logic which is a formal system for the specification and verification of programs, and that is, currently, the base of most of the tools for checking program correctness. The equational theory of KAT is PSPACE-complete and can be reduced to the equational theory of KA, with an exponential cost [8, 14]. Regular sets of guarded strings are standard models for KAT (as regular languages are for KA). The decidability, conciseness and expressiveness of KAT, motivated its recent automatization within several theorem provers [16, 17, 4] and functional languages [3]. Those implementations use (variants of) the coalgebraic automata on guarded strings developed by Kozen [13]. In this approach, derivatives are considered over symbols of the from \( \alpha p \), where \( p \) is an alphabetic symbol (program) and \( \alpha \) a valuation of boolean variables (the guard, normally called atom). This induces an exponential blow-up on the number of states or transitions of the automata and an accentuated exponential complexity when testing the equivalence of two KAT expressions. Recently, Silva [18] introduced an automata model for KAT expressions that extends Glushkov’s construction for regular expressions. In this automata, transitions are labeled with KAT expressions of the form \( bp \), where \( b \) is a boolean expression (and not an atom) and \( p \) an alphabetic symbol. Using similar ideas, Broda et al. [6] extended the Mirkin’s equation automata to KAT expressions and studied the state complexity of both algorithms.
Contrary to other automata constructions for KAT expressions, these two constructions enjoy the same descriptive complexity behaviour as their counterparts for regular expressions, both in the worst-case as well as in the average-case. In this paper, we generalize, for these automata, the classical methods of subset construction for nondeterministic finite automata, and the Hopcroft and Karp algorithm for testing deterministic finite automata equivalence. As a result, we obtain a decision procedure for KAT equivalence where the extra burden of dealing with boolean expressions avoids the explicit use of all possible assignments to the boolean variables. Finally, we specialize the decision procedure for testing KAT expressions equivalence without explicitly constructing the automata, by introducing a new notion of derivative and a new method of constructing the equation automaton.

2 KAT Expressions, Automata, and Guarded Strings

Let $P = \{p_1, \ldots, p_k\}$ be a non-empty set, usual referred to as the set of program symbols, and $T = \{t_0, \ldots, t_{i-1}\}$ be a non-empty set of test symbols. The set of boolean expressions over $T$ together with negation, disjunction and conjunction, is denoted by $\text{BExp}$, and the set of KAT expressions with disjunction, concatenation, and Kleene star, by $\text{Exp}$. The abstract syntax of KAT expressions, over an alphabet $P \cup T$, is given by the following grammar, where $p \in P$ and $t \in T$,

$$
\begin{align*}
\text{BExp} & : \quad b \rightarrow 0 \mid 1 \mid t \mid \neg b \mid b + b \mid b \cdot b \\
\text{Exp} & : \quad e \rightarrow p \mid b \mid e + e \mid e \cdot e \mid e^*.
\end{align*}
$$

As usual, we will omit the operator $\cdot$ whenever it does not give rise to any ambiguity. For the negation of test symbols we frequently use $\overline{t}$ instead of $\neg t$. The set $\text{At}$, of atoms over $T$, is the set of all boolean assignments to all elements of $T$, $\text{At} = \{x_0 \cdots x_{i-1} \mid x_i \in \{t_i, \overline{t_i}\}, \ t_i \in T\}$. Each atom $\alpha \in \text{At}$ has associated a binary word of $l$ bits $(w_0 \cdots w_{l-1})$ where $w_i = 0$ if $t_i \in \alpha$, and $w_i = 1$, if $t_i \in \alpha$.

Now, the set of guarded strings over $P$ and $T$ is $\text{GS} = (\text{At} \cdot P)^* \cdot \text{At}$. Regular sets of guarded strings form the standard language-theoretic model for KAT [12]. For $x = \alpha_1 p_1 \cdots p_{m-1} \alpha_m, y = \beta_1 q_1 \cdots q_{n-1} \beta_n \in \text{GS}$, where $m, n \geq 1$, $\alpha_i, \beta_j \in \text{At}$ and $p_i, q_j \in P$, we define the fusion product $x \ast y = \alpha_1 p_1 \cdots p_{m-1} \alpha_m q_1 \cdots q_{n-1} \beta_n$, if $\alpha_m = \beta_1$, leaving it undefined, otherwise. For sets $X, Y \subseteq \text{GS}$, $X \ast Y$ is the set of all $x \ast y$ such that $x \in X$ and $y \in Y$. Let $X^0 = \text{At}$ and $X^{n+1} = X \ast X^n$, for $n \geq 0$. Given a KAT expression $e$, we define $\text{GS}(e) \subseteq \text{GS}$ inductively as follows:

$$
\begin{align*}
\text{GS}(p) & = \{ \alpha \beta \mid \alpha, \beta \in \text{At} \} \\
\text{GS}(b) & = \{ \alpha \mid \alpha \in \text{At} \land \alpha \leq b \} \\
\text{GS}(e_1 + e_2) & = \text{GS}(e_1) \cup \text{GS}(e_2) \\
\text{GS}(e_1 \cdot e_2) & = \text{GS}(e_1) \ast \text{GS}(e_2) \\
\text{GS}(e^*) & = \bigcup_{n \geq 0} \text{GS}(e_1)^n,
\end{align*}
$$

where $\alpha \leq b$ if $\alpha \rightarrow b$ is a propositional tautology. For $E \subseteq \text{Exp}$, let $\text{GS}(E) = \bigcup_{e \in E} \text{GS}(e)$. Given two KAT expressions $e_1$ and $e_2$, we say that they are equivalent, and write $e_1 = e_2$, if $\text{GS}(e_1) = \text{GS}(e_2)$.

A (non-deterministic) automaton with tests (NTA) over the alphabets $P$ and $T$ is a tuple $\mathcal{A} = (S, s_0, o, \delta)$, where $S$ is a finite set of states, $s_0 \in S$ is the initial state, $o : S \rightarrow \text{BExp}$ is the output function, and $\delta \subseteq 2^{S \times (\text{BExp} \times P)} \times S$ is the transition relation. We denote by $P_{\mathcal{A}}$ and $\text{BExp}_{\mathcal{A}}$, respectively, the set of program symbols and the set of boolean expressions that occur in $\mathcal{A}$. Formally, given an NTA $\mathcal{A} = (S, s_0, o, \delta)$, one can naturally associate to the transition relation $\delta \subseteq 2^{S \times (\text{BExp} \times P)} \times S$ a function $\delta' : S \times (\text{At} \cdot P) \rightarrow 2^S$, defined by $\delta'(s, o\alpha) = \{ s' \mid (s, (b, p), s') \in \delta, \alpha \leq b \}$. And, one can define a function $\delta : S \times \text{GS} \rightarrow \{0, 1\}$ over pairs of states and guarded strings as follows

$$
\delta(s, \alpha) = \begin{cases} 
1 & \text{if } \alpha \leq o(s), \\
0 & \text{otherwise,}
\end{cases}
$$

$$
\tilde{\delta}(s, o\alpha x) = \sum_{s' \in \delta'(s, o\alpha)} \tilde{\delta}(s', x).
$$
Given a state \( s \), \( \text{GS}(s) = \{ x \in \text{GS} \mid \hat{\delta}(s, x) = 1 \} \) is the set of guarded strings accepted by \( s \), and \( \text{GS}(\mathcal{A}) = \text{GS}(\mathcal{A}_0) \). We say that a KAT expression \( e \in \text{Exp} \) is equivalent to an automaton \( \mathcal{A} \), and write \( e = \mathcal{A} \), if \( \text{GS}(\mathcal{A}) = \text{GS}(e) \).

**Example 1.** Given the KAT expression \( e = t_1p(q^*t_2 + t_3q)^* \), an equivalent NTA \( \mathcal{A} \), obtained by the equation algorithm (see [6]), is the following, where \( e_0 = e \), \( e_1 = (pq^*t_2 + t_3q)^* \) and \( e_2 = q^*t_2(pq^*t_2 + t_3q)^* \). Both objects accept the guarded string \( t_1t_2t_3pt_1t_2t_3pt_1t_2t_3qt_1t_2t_3 \).

\[
\begin{align*}
\gamma & \quad \downarrow \quad (1, p) \\
\epsilon & \quad \downarrow \quad 0 \\
\epsilon & \quad \downarrow \quad (t_2, t_3, q) \\
\epsilon & \quad \downarrow \quad (t_1, p) \\
\gamma & \quad \downarrow \quad (1, p) \\
\epsilon & \quad \downarrow \quad (t_2, p, 1, q)
\end{align*}
\]

An NTA is called deterministic (DTA) if and only if for every pair \((\alpha, p) \in \mathcal{A} \times \mathcal{P} \) and every state \( s \in S \), there is at most one transition \((s, (b, p), s') \in \delta \) such that \( \alpha \leq b \), i.e. \( \delta'(s, \alpha p) \) is either empty or a singleton.

### 3 Determinization

The standard subset construction for converting a nondeterministic finite automaton (NFA) into an equivalent deterministic finite automaton (DFA) may be adapted as follows. Given a set of states \( X \subseteq S \), whenever there are transitions \((s_1, (b, p), s_1'), \ldots, (s_m, (b, p), s_m')\), with \( s_1, \ldots, s_m \in X \), in the NTA, in the equivalent DTA we consider “disjoint” transitions to subsets \( \{s_1', \ldots, s_m'\} \subseteq \{s_1, \ldots, s_m\} \), labeled by \((b_1 \cdots b_k - b_{k+1} \cdots - b_m)p\), where \( \{s_{i_{k+1}}, \ldots, s_{i_m}\} = \{s_1, \ldots, s_m\} \setminus \{s_{i_1}, \ldots, s_{i_k}\} \).

Consider the set of atoms \( \mathcal{A} = \{a_0, \ldots, a_{2^d-1}\} \), with the natural order induced by their binary representation. We define the function

\[
\begin{align*}
V & : \text{BExp} \longrightarrow 2^{\{0, \ldots, 2^d-1\}} \\
& b \quad \mapsto \quad V_b = \{ i \mid \alpha_i \leq b, 0 \leq i \leq 2^d-1 \} \\
\end{align*}
\]

This representation of boolean expressions is such that \( V_b = V_{b'} \) if and only if \( b \) and \( b' \) are logically equivalent expressions. We consider \( V_b \) as a canonical representation of \( b \) and write \( \alpha_i \leq V_b \) if and only if \( i \in V_b \). Conversely, to each \( U \subseteq \{0, \ldots, 2^d-1\} \) we associate a unique boolean expression \( B(U) \), where

\[
B : 2^{\{0, \ldots, 2^d-1\}} \longrightarrow \text{BExp}
\]

\[
U \quad \longmapsto \quad \sum_{i \in U} \alpha_i.
\]

For \( b, b' \in \text{BExp} \), we have \( V_{b \wedge b'} = V_b \cup V_{b'} \) and \( V_{b \vee b'} = V_b \cap V_{b'} \), where \( U = \{0, \ldots, 2^d-1\} \setminus U \) for any \( U \subseteq \{0, \ldots, 2^d-1\} \).

**Example 2.** For \( T = \{t_1, t_2\} \) and \( \mathcal{A} = \{t_1t_2, t_1t_2, t_1t_2, t_1t_2\} \), we have \( V_{t_1} = \{1, 3\} \) and \( V_{t_1 \rightarrow t_2} = \{0, 1, 3\} \). Also, \( B(1, 3) = t_1t_2 \).

We now describe the subset construction that, given an NTA, \( \mathcal{A} = \langle S, s_0, o, \delta \rangle \), over the alphabets \( \mathcal{P} \) and \( T \), produces an DTA, \( \mathcal{A}_{\text{det}} = \langle 2^S, \{s_0\}, o_{\text{det}}, \delta_{\text{det}} \rangle \), over \( \mathcal{P} \) and \( T \), such that \( \text{GS}(\mathcal{A}) = \text{GS}(\mathcal{A}_{\text{det}}) \).

First, we define two functions

\[
\hat{\delta}_{\text{det}} : 2^S \times (2^{\{0, \ldots, 2^d-1\}} \times \mathcal{P}) \longrightarrow 2^S \quad \text{and} \quad \hat{o}_{\text{det}} : 2^S \longrightarrow 2^{\{0, \ldots, 2^d-1\}}.
\]

Then, we take \( \delta_{\text{det}} = \{ (X, (B(V, p), Y)) \mid (X, (V, p), Y) \in \hat{\delta}_{\text{det}} \} \) as well as \( o_{\text{det}} = B \circ \hat{o}_{\text{det}} \). For \( X \subseteq S \), we define \( \delta_{\text{det}}(X) = \bigcup_{s \in X} V_{o(s)} \). To define \( \hat{\delta}_{\text{det}} \), we consider the following sets. Given \( X \subseteq S \) and \( p \in \mathcal{P} \), let

\[
\Gamma(X, p) = \{ (b, s') \mid (s, (b, p), s') \in \delta, \quad s \in X \}.
\]

\[
\Delta(X, p) = \{ s' \mid (b, s') \in \Gamma(X, p) \}.
\]
Finally, we have
\[
\hat{\delta}_{\text{det}} = \{ (X, (V_{X,p,Y}, Y), Y) \mid X \subseteq S, Y \subseteq \Delta(X,p), p \in P, V_{X,p,Y} \neq \emptyset \}.
\]

**Proposition 3.** For every NTA \( \mathcal{A} = (S, s_0, o, \delta) \), the automaton \( \mathcal{A}_{\text{det}} = (S, s_0, o_{\text{det}}, \hat{\delta}_{\text{det}}) \) is deterministic.

**Proof.** For all \( X, Y \subseteq S \) and \( p \in P \), the set \( V_{X,p,Y} \) is uniquely defined (and equal to \( \emptyset \), if \( X = \emptyset \) or \( Y = \emptyset \)). Thus, it remains to show that whenever \( (X, (V_{X,p,Y}, Y), (X, (V_{X,p,Y'}, p), Y')) \in \hat{\delta}_{\text{det}} \), for some non-empty sets \( X, Y, Y' \subseteq S, Y \neq Y' \) and \( p \in P \), then \( V_{X,p,Y} \cap V_{X,p,Y'} = \emptyset \). Since \( Y \neq Y' \), there is some \( s' \in S \) such that \( s' \in Y \) and \( s' \notin Y' \) (or vice-versa). By the definition of \( V_{X,p,Y} \), we conclude that \( V_{X,p,Y} \subseteq V_{X,p,Y'} \) and \( V_{X,p,Y'} \subseteq V_{X,p,Y} \). Thus, \( V_{X,p,Y} \cap V_{X,p,Y'} = \emptyset \). \( \square \)

**Corollary 4.** For every NTA \( \mathcal{A} = (S, s_0, o, \delta) \), \( X \subseteq S, \alpha \in \text{At} \) and \( p \in P \), the set \( \delta'_{\text{det}}(X, \alpha p) \) is either \( \emptyset \) or a singleton \( \{ Y \} \), where \( Y = \{ s' \mid (b, s') \in \Gamma(X,p), \alpha \leq b \} \).

**Proof.** By definition, \( \delta'_{\text{det}}(X, \alpha p) = \{ Y \mid (X, (V_{X,p,Y}, p), Y) \in \hat{\delta}_{\text{det}}, \alpha \leq V_{X,p,Y} \} \) and has to be either \( \emptyset \) or a singleton since \( \mathcal{A}_{\text{det}} \) is deterministic. Furthermore, it follows, by the construction of \( V_{X,p,Y} \), that one has \( (X, (V_{X,p,Y}, p), Y) \in \hat{\delta}_{\text{det}} \) and \( \alpha \leq V_{X,p,Y} \) if and only if \( Y \) is exactly the set of states \( s' \) such that for some \( b \in \text{BExp} \) there is \( (b, s') \in \Gamma(X,p) \) with \( \alpha \leq b \). \( \square \)

**Proposition 5.** For \( \mathcal{A} = (S, s_0, o, \delta) \) one has \( \text{GS}(\mathcal{A}) = \text{GS}(\mathcal{A}_{\text{det}}) \).

**Proof.** We will prove that for every set of states \( X \subseteq S \) and every guarded string \( x \in \text{GS} \), one has \( \hat{\delta}_{\text{det}}(X) = \sum_{s \in X} \hat{\delta}(s, x) \). Thus, in particular \( \hat{\delta}_{\text{det}}(\{ s_0 \}, x) = \hat{\delta}(s_0, x) \). The proof is by induction on the number of action symbols in \( x \).

For \( x = \alpha \) we have \( \sum_{s \in X} \hat{\delta}(s, \alpha) = 1 \) if and only if there is some \( s \in X \) such that \( \alpha \leq o(s) \), i.e. \( \alpha \leq V_{o(s)} \). This is equivalent to \( \alpha \leq o_{\text{det}}(X) \), hence to \( \hat{\delta}_{\text{det}}(X, \alpha) = 1 \). For \( x = \alpha py \), we have
\[
\sum_{s \in X} \hat{\delta}(s, \alpha py) = \sum_{s' \in \bar{\delta}(s, \alpha p)} \sum_{s'' \in Y} \hat{\delta}(s'', y) = \sum_{s' \in \bar{\delta}(s, \alpha p)} \sum_{s'' \in Y} \hat{\delta}(s'', y),
\]
where \( Y = \{ s' \mid (b, s') \in \Gamma(X,p), \alpha \leq b \} \). By the induction hypothesis, we conclude that \( \sum_{s \in X} \hat{\delta}(s, \alpha py) = \sum_{s'' \in Y} \hat{\delta}(s'', y) = \hat{\delta}_{\text{det}}(Y, y) \). On the other hand, it follows from Corollary 4 that \( \hat{\delta}_{\text{det}}(X, \alpha py) = \hat{\delta}_{\text{det}}(Y, y) \), with \( Y = \{ s' \mid (b, s') \in \Gamma(X,p), \alpha \leq b \} \). \( \square \)

**Example 6.** Applying the construction above to the NTA from Example 1, we obtain the following DTA:

![Diagram](image-url)

To illustrate the construction, we first consider the subset \( X = \{ e_2 \} \) and program symbol \( q \). We have
\[
\Gamma(\{ e_2 \}, q) = \{ (t_2 t_3, e_1), (1, e_2) \} \quad \text{and} \quad \Delta(\{ e_2 \}, q) = \{ e_1, e_2 \}.
\]
Hence, we conclude that

\[ V_{\{e_1\}, q, e_1} = \{0, 4\} \quad \text{and} \quad V_{\{e_2\}, q, e_2} = \{0, \ldots, 7\}. \]

Regarding \( X = \{e_1, e_2\} \), we have

\[ \Gamma(\{e_1, e_2\}, q) = \{(t_3, e_1), (t_2 t_3, e_1), (1, e_2)\} \quad \text{and} \quad \Delta(\{e_1, e_2\}, q) = \{e_1, e_2\}. \]

Furthermore,

\[ V_{\{e_1, e_2\}, q, e_1} = \{0, 2, 4, 6\} \quad \text{and} \quad V_{\{e_1, e_2\}, q, e_2} = \{0, \ldots, 7\}. \]

Finally,

\[ V_{\{e_1, e_2\}, q, \{e_1, e_2\}} = \bigcap \{\{0, 2, 4, 6\}, \{0, \ldots, 7\}\} = \{0, 2, 4, 6\} = V_{t_5} \]

and

\[ V_{\{e_1, e_2\}, t, \{e_1, e_2\}} = \bigcap \{\{0, 2, 4, 6\}, \{\}\}\} = \{\} \quad \text{and} \quad V_{\{e_1, e_2\}, t, \{e_1, e_2\}} = \bigcap \{\{0, \ldots, 7\}, \{1, 3, 5, 7\}\} = \{1, 3, 5, 7\} = V_{\sim t_3}. \]

### 3.1 Implementation and Complexity

It is important to notice that in the determination algorithm, the construction of all the \(2^{|S|}\) subsets \( X \) of the set of states \( S \) can be avoided by considering only reachable states from the initial state. In order to, efficiently deal with boolean operations it is essential to have an adequate representation for the boolean expressions \( b \) as well as the sets \( V_b \). A possible choice is to use OBDDs (ordered binary decision diagrams), for which there are several software packages available. The sets \( V_{X, p, Y} \) may also be constructed using a (variant) of the standard Quine-McCluskey algorithm.

In the worst case, the determination algorithm exhibits an extra exponential complexity to compute the sets \( V_{X, p, Y} \). The deterministic automaton \( \mathcal{A}_{det} \) has at most \( 2^m \) states and \( 2^{m} 2^{k} \) transitions where \( n = |S|, l = |T|, \) and \( k = |P| \). Contrary to what happens with the other KAT automata where the set \( \mathcal{A} \) is explicitly used, in practice and with adequate data structures, we can expect that the number of sets \( X \subseteq S \) and of sets \( V_{X, p, Y} \) is kept within tractable limits. It is an open problem to theoretically obtain the average-case complexity of both the power set construction and the sets \( V_{X, p, Y} \).

### 4 Equivalence of Deterministic Automata

Hopcroft and Karp [10] presented an almost linear algorithm (HK) for testing the equivalence of two DFAs that avoids their minimization. Considering the merge of the two DFAs as a single one, the algorithm computes the finest right-invariant relation, on the set of states, that makes the initial states equivalent. Recently this algorithm was analyzed and extended to NFAs in [2, 35]. In this section, we extend it, again, for testing equivalence of deterministic automata for guarded strings.

We will only consider DTAs, \( \mathcal{A} = \langle S, s_0, o, \delta \rangle \), where all states are useful, i.e. for every state \( s \in S \), \( GS(s) \neq \emptyset \).

Given a DTA, \( \mathcal{A} = \langle S, s_0, o, \delta \rangle \), over the alphabets \( P \) and \( T \), and \( s, t \in S \), we say that \( s \) and \( t \) are equivalent, and write \( s \approx t \), if \( GS(s) = GS(t) \). A binary relation \( R \) on \( S \) is right invariant if for all \( s, t \in S \) if \( sRt \) then the following conditions hold:

\[ \forall \alpha \in At, \ a \leq o(s) \Leftrightarrow \alpha \leq o(t); \]

\[ \forall op \in At \cdot P, \ (\delta'(s, op) = \delta'(t, op) = \emptyset) \text{ or } (\delta'(s, op) = \{s'\}, \delta'(t, op) = \{t'\}) \text{ and } s'Rt'. \]
It is easy to see that the relation $\approx$ is right invariant. Furthermore, whenever $R$ is a right-invariant relation on $S$ and $sRt$, for $s, t \in S$, one has $s \approx t$.

Let $A_1 = \langle S_1, s_0, o_1, \delta_1 \rangle$ and $A_2 = \langle S_2, r_0, o_2, \delta_2 \rangle$ be two DTAs over the alphabets $P$ and $T$, such that $S_1 \cap S_2 = \emptyset$. The algorithm HK, given below, decides if these two automata are equivalent, i.e. if $GS(A_1) = GS(A_2)$, by building a right-invariant relation that checks whether $s_0 \approx r_0$. Consider $A = \langle S, s_0, o, \delta \rangle$, where

$$S = S_1 \cup S_2, \quad o(s) = \begin{cases} o_1(s) & \text{if } s \in S_1 \quad \text{and } \delta = \delta_1 \cup \delta_2. 
\end{cases}$$

**Lemma 7.** Given two DTAs, $A_1$ and $A_2$, let $A$ be defined as above. Then, $s_0 \approx r_0$ (in $A$) if and only if $GS(A_1) = GS(A_2)$.

The algorithm uses an initially empty stack $H$ and a set partition $P$ of $S$, which are both updated during the computation. The set partition $P$ is built using the UNION-FIND data structure [9]. Within this structure, three functions are defined:

- **MAKE(i)**: creates a new set (singleton) for one element $i$ (the identifier);
- **FIND(i)**: returns the identifier $S_i$ of the set which contains $i$;
- **UNION(i, j, k)**: combines the sets identified by $i$ and $j$ into a new set $S_k = S_i \cup S_j$; $S_i$ and $S_j$ are destroyed.

An arbitrary sequence of $i$ operations MAKE, UNION, and FIND, of which are MAKE operations, necessary to create the required sets can, in worst-case, be performed $O(i\alpha(j))$ time, where $\alpha(j)$ is related to a functional inverse of the Ackermann function, and, as such, grows very slowly, and for practical uses can be considered a constant. In the whole we assume that whenever FIND(i) fails, MAKE(i) is called.

**Algorithm 1: HK algorithm for deterministic automata.**

```
def HK(A_1, A_2):
    MAKE(s_0); MAKE(r_0)
    H = \emptyset
    UNION(s_0, r_0, r_0); PUSH(H, (s_0, r_0))
    while (s, t) = POP(H):
        if \( V_{\alpha(s)} \neq V_{\alpha(t)} \):
            return False
        for p \in P:
            B_1 = \Gamma(\{s\}, p)
            B_2 = \Gamma(\{t\}, p)
            if \( \bigcup_{(b_1, \cdot) \in B_1} V_{b_1} = \bigcup_{(b_2, \cdot) \in B_2} V_{b_2} \):
                for (b_1, s') \in B_1:
                    for (b_2, t') \in B_2:
                        if \( V_{b_1} \cap V_{b_2} \neq \emptyset \):
                            s' = FIND(s')
                            t' = FIND(t')
                            if \( s' \neq t' \):
                                UNION(s', t', t')
                                PUSH(H, (s', t'))
            else:
                return False
    return True
```

The algorithm terminates because every time it pushes a pair onto the stack it performs a union of two disjoint sets in the partition, and this can be done at most $|S| - 1$ times. Given that set operations introduce what can be considered a constant time factor, the worst-case running time of the algorithm HK is $O(m^2 kn)$, where $n = |S|, k = |P_A|$, and $m = |\text{BE}_\text{exp}_A|$. The correctness of this version of algorithm HK is given by the proposition below, whose proof follows closely the one for DFAs.
Definition 8. We define a binary relation $\sim_{HK} \subseteq S \times S$ by $s \sim_{HK} t$ if $\text{FIND}(s) = \text{FIND}(t)$, when the algorithm terminates and returns True.

This relation is obviously an equivalence relation.

Lemma 9. The relation $\sim_{HK}$ is right invariant.

Proof. If $s \sim_{HK} t$ and $s \neq t$, then there exists a sequence of states $s = q_1, q_2, \ldots, q_n = t \in \text{FIND}(s)$, with $n \geq 2$, such that either $(q_i, q_{i+1}) \in H$ or $(q_{i+1}, q_i) \in H$ at some point of the computation, for $i = 1, \ldots, n - 1$. Since $V_{o(q_i)} = V_{o(q_{i+1})}$ (otherwise the algorithm would have failed in line 6), we have $\forall \alpha \in \text{At} \quad \alpha \leq o(q_i) \Leftrightarrow \alpha \leq o(q_{i+1})$. Furthermore, it follows from the test in line 10 and from the automaton being deterministic, that $\forall \alpha \in \text{At} \cdot \text{P}$ either $\delta'(q_i, \alpha p) = \delta'(q_{i+1}, \alpha p) = \emptyset$ or $\delta'(q_i, \alpha p) = \{s', \delta'(q_{i+1}, \alpha p) = \{t'\}$. In this last case, there exist $(q_i, (b_1, p), s'), (q_{i+1}, (b_2, p), t') \in \delta$ such that $\alpha \leq b_1 \cdot b_2$. Consequently, either one has already $\text{FIND}(q_i) = \text{FIND}(q_{i+1})$, or $(s', t')$ enters $H$ and one has $\text{FIND}(q_i) = \text{FIND}(q_{i+1})$ afterwards. Thus, $s' \sim_{HK} t'$. Since these properties are true for all $i = 1, \ldots, n - 1$, we conclude that $\forall \alpha \in \text{At} \quad \alpha \leq o(s) \Leftrightarrow \alpha \leq o(t)$. Furthermore, $\forall \alpha \in \text{At} \cdot \text{P}$ either $\delta'(s, \alpha p) = \delta'(t, \alpha p) = \emptyset$ or $\delta'(s, \alpha p) = \{s'\}, \delta'(t, \alpha p) = \{t'\}$ and $s \sim_{HK} t$. \qed

Proposition 10. The algorithm returns True if and only if $s_0 \sim r_0$.

Proof. If the algorithm returns True, then $s_0 \sim_{HK} r_0$. Since $\sim_{HK}$ is right invariant, we conclude that $s_0 \sim r_0$.

If $s_0 \not\sim r_0$, then there is some $x = \alpha_1 p_1 \ldots \alpha_n p_n \alpha \in \text{GS}$, such that $\delta(s_0, x) = 1$ and $\delta(r_0, x) = 0$ (or vice-versa). $\delta(s_0, x) = 1$ implies that there are $s_1, \ldots, s_n \in S$ such that $\alpha_1 \leq o(s_n)$ and for $i = 1, \ldots, n$, there is $(s_{i-1}, (b_i, p_i), s_i) \in \delta$ with $\alpha_i \leq b_i$. One reason for $\delta(r_0, x) = 0$ is the existence of $k \in \{1, \ldots, n-1\}$ such that $t_1, \ldots, t_k \in S$ such that for $i = 1, \ldots, k$, there is $(t_{i-1}, (b'_i, p_i), t'_i) \in \delta$ with $\alpha_i \leq b'_i$, but there is no $(t_k, (b'_{k+1}, p_{k+1}), t'_{k+1}) \in \delta$ with $\alpha_{k+1} \leq b'_{k+1}$. In this case, it is easy to verify, by induction on $k$, that one has $\text{FIND}(s_1) = \text{FIND}(t_1), \ldots, \text{FIND}(s_k) = \text{FIND}(t_k)$, but the algorithm will fail in step 10 after constructing $B_1$ and $B_2$ respectively for $s = \text{FIND}(s_k)$ and $t = \text{FIND}(t_k)$ (this, in case it has not already failed before). The other possible reason is that there are actually $t_1, \ldots, t_n \in S$ such that for $i = 1, \ldots, n$, there is $(t_{i-1}, (b'_i, p_i), t_i) \in \delta$ with $\alpha_i \leq b'_i$, but $\alpha \not\leq o(t_n)$. In this case, the algorithm fails at step 6. \qed

5 Equivalence of Nondeterministic Automata

We can embed the determinization process directly into the HK algorithm, extending it, so that it can be used to test the equivalence of NTAs. As before, given two NTAs with disjoint sets of states, $A_1$ and $A_2$, we consider them as a single NTA, $A = (S, s_0, o, \delta)$. We denote the resulting algorithm by HKN.

Algorithm 2: HKN algorithm for nondeterministic automata.

```python
def HKN(A1, A2):
    MAKE({s0}) : MAKE({r0})
    H = ∅
    UNION({s0}, {r0}, {r0}) : PUSH(H, ({s0}, {r0}))
    while (X, Y) = POP(H):
        if δdet(X) ≠ δdet(Y) : return False
        for p ∈ P:
            B1 = Γ(X, p)
            B2 = Γ(Y, p)
        if ∪ (b1, b2) ∈ B1 ∪ (b2, b1) ∈ B2
            for X' ⊆ Δ(X, p):
                for Y' ⊆ Δ(Y, p):
                    if ∪ vX,y,x ∩ ∪ vY,p,y' ≠ ∅:
                        X' = FIND(X')
                        Y' = FIND(Y')
```

8
6 Equivalence of KAT Expressions

Given two KAT expressions, \( e_1 \) and \( e_2 \), their equivalence can be tested by first converting each expression to an equivalent NTA and then, either by determining both and applying the HK algorithm (Section 4), or by directly using the resulting NTAs in algorithm HKN (Section 5). In particular, we could use the equation construction given in [6] to obtain NTAs equivalent to the given KAT expressions and then apply the HKN algorithm. The equation automata for KAT expressions is an adaptation of Mirkin’s construction [15] for regular expressions. Given \( e_0 = e \in \text{Exp} \), a set of KAT expressions \( \pi(e) = \{ e_1, \ldots, e_n \} \) is defined inductively by \( \pi(p) = \{ 1 \} \), \( \pi(b) = \emptyset \), \( \pi(e + f) = \pi(e) \cup \pi(f) \), \( \pi(e \cdot f) = \pi(e) \cdot \pi(f) \), and \( \pi(e^*) = \pi(e)^* \). This set satisfy the following system of equations

\[
e_i = \sum_{j=1}^{n} b_{ij} p_j e_j + \cdots + \sum_{j=1}^{n} b_{ijk} p_k e_j + \text{out}(e_i) \quad (1)
\]

for \( i = 0, \ldots, n, \ p_r \in P, \ k = |P| \), some \( b_{ijr} \in \text{BExp} \), and where function \text{out} is defined below. The equation automaton is \( A_{eq}(e) = \{ \{ e \} \cup \pi(e), e, \text{out}, \delta_{eq} \} \) with \( \delta_{eq} = \{ (e_i, (b_{ijr}, p_r), e_j) \mid \text{if } b_{ijr} p_r e_j \text{ is a component of the equation for } e_i \} \).

In this section, we will use this construction to define an algorithm for testing equivalence of KAT expressions by a recursive computation of their derivatives without explicitly building any automaton. However, the correctness of this procedure is justified by the correctness of the equation automaton. We first present a slightly different formalization of this automaton construction, which is more adequate for our purposes. The construction resembles the partial derivative automaton for regular expressions (that is known to be identical to the Mirkin automaton [7]). The resulting decision procedure for KAT equivalence is also similar to the ones recently presented for regular expressions (see [1, 2]) and can be seen as a syntactic (and more compact) version of the one presented by Kozen [13].

For \( e \in \text{Exp} \) and a program symbol \( p \in P \), the set \( \partial_p(e) \) of partial derivatives of \( e \) w.r.t. \( p \) is inductively defined as follows:

\[
\partial_p : \text{Exp} \rightarrow \text{BExp} \times \text{Exp}
\]

\[
\partial_p(p') = \begin{cases} 
\{(1,1)\} & \text{if } p' \equiv p \\
\emptyset & \text{otherwise}
\end{cases}
\]

\[
\partial_p(b) = \emptyset
\]

where \( \text{out} : \text{Exp} \rightarrow \text{BExp} \) is defined by

\[
\text{out}(p) = 0 \quad \text{out}(e_1 + e_2) = \text{out}(e_1) + \text{out}(e_2) \quad \text{out}(e^*) = 1
\]

and for \( R \subseteq \text{BExp} \times \text{Exp}, \ e \in \text{Exp}, \) and \( b \in \text{BExp}, \ Re = \{ (b', e') \mid (b', e') \in R \} \) and \( bR = \{ (bb', e') \mid (b', e') \in R \} \). We also define \( \Delta_p(e) = \{ e' \mid (b, e') \in \delta_p(e) \} \). The functions \( \partial_p \), \( \text{out} \), and \( \Delta_p \) are naturally extended to sets \( X \subseteq \text{Exp} \). Moreover we define the KAT expression \( \sum \partial_p(e) \equiv \sum_{(b, e_i) \in \delta_p(e)} b_{pe_i} \).

Example 11. The states of the equation automaton in Example 1 satisfy the following system of equations:

\[
e_0 = t_1 p e_1
\]

\[
e_1 = 1 p e_2 + t_3 q e_1 + 1
\]

\[
e_2 = t_2 p e_2 + t_2 t_3 q e_1 + 1 q e_2 + t_2
\]

For instance, note that \( \partial_p(e_2) = \{(t_2, e_2)\}, \partial_q(e_2) = \{(t_2 t_3, e_1), (1, e_2)\}, \text{out}(e_2) = t_2, \) and \( e_2 = \sum \partial_p(e_2) + \sum \partial_q(e_2) + \text{out}(e_2) \).
Given $e \in \text{Exp}$, we define the \textit{partial derivative} automaton $A_{\text{pd}}(e) = \langle \{e\} \cup \pi(e), e, \delta_{\text{pd}}, \text{out}(e) \rangle$ where $\delta = \{ (e_1,(b,p),e_2) \mid p \in P, (b,e_2) \in \partial_p(e_1) \}$.

Lemma 12. For $e \in \text{Exp}$, $A_{\text{pd}}(e)$ and $A_{\text{eq}}(e)$ are identical.

Proof. The set $\pi(e) = \{e_1, \ldots, e_n\}$ as defined for the equation automata $A_{\text{eq}}(e)$ [6] satisfies equation (1) and has the following inductive definition: $\pi(p) = \{1\}, \pi(b) = \emptyset, \pi(e + f) = \pi(e) \cup \pi(f)$, $\pi(e \cdot f) = \pi(e)f \cup \pi(f)$, and $\pi(e^*) = \pi(e)e^*$. We have to show that for all $i = 0, \ldots, n$ and $p_r \in P$, $\sum \partial_{p_i}(e_i) \equiv \sum_{j=1}^{n} b_{ijr} p_i e_j$. These can be proved by induction on the structure of $e$. \qed

Proposition 13. $\text{GS}(A_{\text{pd}}(e)) = \text{GS}(e)$.

Now, it is easy to see that we can define a procedure, HKK, that directly tests the equivalence of any given two KAT expressions. For that, it is enough to modify HKN by taking $\langle \{e_1\}, \{e_2\} \rangle$ as the initial pair and, for $X \subseteq \text{Exp}$, $\delta_{\text{det}}(X) = \text{out}(X), \Gamma(X, p) = \partial_p(X)$ and $\Delta(X, p) = \Delta_p(X)$.

### Algorithm 3: HKK algorithm for KAT expressions.

```plaintext
1 def HKK(e1, e2):
2 MAKE({e1}) ; MAKE({e2})
3 H = ∅
4 UNION({e1}, {e2}, {e1}) ; PUSH(H, ({e1}, {e2}))
5 while (X,Y) = POP(H):
6 if out(X) ≠ out(Y): return False
7 for p ∈ P:
8 B1 = ∂p(X)
9 B2 = ∂p(Y)
10 if \( \bigcup_{b1} V_{b1} = \bigcup_{b2} V_{b2} \):
11 for X′ ⊆ Δp(X):
12 for Y′ ⊆ Δp(Y):
13 if \( \forall X′, Y′, \exists V_{X′, Y′} \neq ∅ \):
14 X′ = FIND(X′)
15 Y′ = FIND(Y′)
16 if X′ ≠ Y′:
17 UNION(X′, Y′, Y′)
18 PUSH(H, (X′, Y′))
19 else: return False
20 return True
```

7 Conclusions

We considered an automata model for KAT expressions where each transition is labeled by a program symbol and, instead of an atom, a boolean expression. Each transition can, thus, be seen as labeled, in a compact way, by a set of atoms, the ones that satisfy the appropriate boolean expression. Recently, symbolic finite automata (SFA) where transitions are labeled with sets of alphabetic symbols were introduced in order to deal with large alphabets [19]. Although the extension of classical finite automata algorithms to SFAs bears similarities with the ones here presented, SFAs are interpreted over sets of finite words and not over sets of guarded strings. Experiments with the algorithms presented in this paper must be carried out in order to validate their practical applicability and also to suggest goals for a theoretical study of their average-case complexity.
