#### Abstract

Computing short regular expressions equivalent to a given finite automaton is a hard task. In this work we present a class of acyclic automata for which it is easy to find a regular expression that has linear size. We call those automata UDR. A UDR automaton is characterized by properties of its underlying digraph. We present a characterisation theorem and an efficient algorithm to determine if an acyclic automaton is UDR. This algorithm can be adapted to compute a short regular expression equivalent to a given UDR automaton.

Keywords: Formal languages, finite automata, regular expressions, graph theory, minimisation

## 1 Introduction

Computing a regular expression from a given finite automaton can be achieved by wellknown algorithms based on Kleene's theorem [Kle56], establishing the equivalence between languages accepted by finite automata and languages represented by regular expressions. However the resulting regular expression depends on the order of the automaton's states considered in the conversion. In particular, this is the case if the algorithm is based on the state elimination technique. Consider, for example, the following automaton:

If we remove the state $q_{2}$ and then the state $q_{3}$, we obtain the regular expression $\mathrm{ad}+(\mathrm{ac}+\mathrm{b}) \mathrm{e}$. But if we remove first $q_{3}$ and then $q_{2}$, we obtain the regular expression $\mathrm{be}+\mathrm{a}(\mathrm{ce}+\mathrm{d})$. In the first case, the symbol a occurs two times, and in the second, the symbol e occurs two times. The first case corresponds to the application of the distributivity rule on the right, and the second to the application of that rule on the left. Although in this example the resulting regular expressions have the same number of symbols, in general that will not be the case. If our goal is to obtain an equivalent regular expression with short size from a given automaton, the order in which we consider the automaton states is of great importance. Moreover, given an automaton with $n$ states and $k$ alphabetic symbols the upper bound for the size of the equivalent regular expression is $O\left(n k 4^{n}\right)$ (and no general smaller lower bounds are known), and the problem of obtaining a minimal regular expression equivalent to a given automaton is PSPACE-complete [JR93].

In this work we present a characterisation of acyclic automata for which it is easy to find an order of state removal such that the resulting regular expressions have size linear in the number of the automata transitions.

The paper is organised as follows. In the next section, we review some basic notions and introduce notation used in this paper. In Section 3 we define a class of acyclic automata that we call UDR. Section 4 gives a characterisation theorem of UDR automata in terms of properties of their underlying digraphs. In Section 5 we show that it is possible to compute a linear size regular expression from a UDR automaton. An efficient algorithm for determining if an automaton is UDR is presented in Section 6. Relationships with other work and with specific classes of finite automata are discussed in Section 7. In the last section, we provide some final remarks.

## 2 Preliminaries

We recall the basics of digraphs, finite automata and regular expressions that can be found in standard books [HMU00, Har69, BJG01]. A digraph $D=(V, E)$ consists of a finite set $V$ of vertices and a set $E$ of ordered pairs of vertices, called $\operatorname{arcs}$. If $(u, v)$ in $E, u$ is adjacent to $v$ and $v$ is adjacent from $u$. For each vertex $v$, the indegree of $v$ is the number $n_{i}$ of vertices adjacent to it and the outdegree of $v$ is the number $n_{o}$ of vertices adjacent from it, and we write $v\left(n_{i} ; n_{o}\right)$. An arc $(u, v)$ can be denoted by $u v$. A path between $v_{0}$ and $v_{n}$ is a sequence $v_{0} v_{1}, v_{1} v_{2}, \ldots, v_{n-1} v_{n}$ of arcs, and is denoted by $v_{0}-v_{n}$, or $v_{0}-v_{k}-v_{n}$, for $1 \leq k<n$. A path is simple if all the vertices in it are distinct. The length of a path is number of arcs in the path. A path is a cycle if $v_{0}=v_{n}$ and $n \geq 1$. A digraph that has no cycles is called acyclic. For an acyclic digraph $D=(V, E)$, there is a topological ordering $o$ of its vertices, i.e., such that if $(u, v) \in E$ then $o(u)<o(v)$.

An alphabet $\Sigma$ is a nonempty set of symbols. A string over an alphabet $\Sigma$ is a finite sequence of symbols of $\Sigma$. The empty string is denoted by $\epsilon$. The set $\Sigma^{\star}$ is the set of all strings over $\Sigma$. A language $L$ is subset of $\Sigma^{\star}$. If $L_{1}$ and $L_{2}$ are two languages, then $L_{1} \cdot L_{2}=\left\{x y \mid x \in L_{1}\right.$ and $\left.y \in L_{2}\right\}$. The operator $\cdot$ is often omitted. A regular expression (r.e.) $\alpha$ over $\Sigma$ represents a (regular) language $L(\alpha) \subseteq \Sigma^{\star}$ and is inductively defined by: $\emptyset$ is a r.e and $L(\emptyset)=\emptyset ; \epsilon$ is a r.e and $L(\epsilon)=\{\epsilon\} ; a \in \Sigma$ is a r.e and $L(a)=\{a\} ;$ if $\alpha_{1}$ and $\alpha_{2}$ are r.e., $\alpha_{1}+\alpha_{2}, \alpha_{1} \alpha_{2}$ and $\alpha_{1}^{\star}$ are r.e., respectively with $L\left(\left(\alpha_{1}+\alpha_{2}\right)\right)=L\left(\alpha_{1}\right) \cup L\left(\alpha_{2}\right)$, $L\left(\left(\alpha_{1} \alpha_{2}\right)\right)=\left(L\left(\alpha_{1}\right) L\left(\alpha_{2}\right)\right)$ and $L\left(\alpha_{1}{ }^{\star}\right)=L\left(\alpha_{1}\right)^{\star}$. Let $R_{\Sigma}$ be the set of regular expressions over $\Sigma$. Two regular expressions $\alpha_{1}$ and $\alpha_{2}$ are equivalent if $L\left(\alpha_{1}\right)=L\left(\alpha_{2}\right)$, and we write $\alpha_{1} \equiv \alpha_{2}$. The algebraic structure $\left(R_{\Sigma},+, \cdot \emptyset, \epsilon\right)$, forms a idempotent semi-ring. i.e., for all $\alpha, \beta, \gamma \in R_{\Sigma}$ we have:

$$
\begin{array}{ll}
\alpha+(\beta+\gamma) \equiv(\alpha+\beta)+\gamma & \alpha+\beta \equiv \beta+\gamma \\
\alpha+\emptyset \equiv \alpha & \alpha+\alpha=\alpha \\
\alpha(\beta \gamma) \equiv(\alpha \beta) \gamma & \alpha \epsilon \equiv \epsilon \alpha \equiv \alpha \\
\alpha(\beta+\gamma) \equiv \alpha \beta+\alpha \gamma & (\alpha+\beta) \gamma \equiv \alpha \gamma+\beta \gamma \\
\alpha \emptyset \equiv \emptyset \alpha \equiv \emptyset &
\end{array}
$$

In this work, we will take the size of a regular expression $\alpha$ to be the number of symbols from $\Sigma$ contained in $\alpha$, and we denote it by $|\alpha|$.

A nondeterministic finite automaton (NFA) $A$ is a quintuple $\left(Q, \Sigma, \delta, q_{0}, F\right)$ where $Q$ is finite set of states, $\Sigma$ is the alphabet, $\delta \subseteq Q \times \Sigma \cup\{\epsilon\} \times Q$ the transition relation, $q_{0}$ the initial state and $F \subseteq Q$ the set of final states. A NFA is deterministic (DFA) if for each pair $(q, a) \in Q \times \Sigma$ there exists at most one $q^{\prime}$ such that $\left(q, a, q^{\prime}\right) \in \delta$. For $q \in Q$ and $a \in \Sigma$, we denote by $\delta(q, a)=\{p:(q, q, p) \in \delta\}$, and we can extend this notation to $x \in \Sigma^{\star}$ and $T \subseteq Q$, by $\delta(q, a x)=\delta(\delta(q, a), x)$. The language accepted by $A$ is $L(A)=\left\{x \in \Sigma^{\star} \mid \delta\left(q_{0}, x\right) \cap F \neq \emptyset\right\}$. Two NFA are equivalent if they accept the same language. The size of a NFA is the number of its transitions.

The underlying digraph of a NFA $A=\left(Q, \Sigma, \delta, q_{0}, F\right)$ is the digraph $D=(Q, E)$ such that $E=\left\{\left(q, q^{\prime}\right) \mid q, q^{\prime} \in Q\right.$ and $\exists a \in \Sigma \cup\{\epsilon\}$ such that $\left.\left(q, a, q^{\prime}\right) \in \delta\right\}$. Note that even there can be more than one symbol of $\Sigma$ between two states $q$ and $q^{\prime}$, only one arc exists in the underlying graph. We call initial vertex the vertex that corresponds to the initial state, final vertices the ones that correspond to final states and intermediate vertices, all the others. An automaton is useful if in its underlying digraph, every vertex is in a path from the initial vertex to a final vertex. An automaton is acyclic if its underlying digraph is acyclic. We will use the above terminology both for digraphs and for automata.

An extended finite automaton (EFA) $A$ is a quintuple $\left(Q, \Sigma, \delta, q_{0}, F\right)$, where $Q, \Sigma, q_{0}$ and $F$ are as before and $\delta: Q \times Q \rightarrow R_{\Sigma}$. We assume that $\delta\left(q, q^{\prime}\right)=\emptyset$, if the transition from $q$ to $q^{\prime}$ is not defined. A string $x \in \Sigma$ is said to be accepted by $A$ if $x=x_{1} \cdots x_{n}$, for $x_{1}, \ldots, x_{n} \in \Sigma^{\star}$ and there is a state sequence $q_{0}, q_{1}, \ldots, q_{n}$ with $q_{n} \in F$, such that $x_{1} \in L\left(\delta\left(q_{0}, q_{1}\right)\right), \ldots, x_{n} \in L\left(\delta\left(q_{n-1}, q n\right)\right)$. The language accepted by $A$ is the set of all strings accepted by $A$. The underlying digraph of a EFA is a digraph $D=(Q, E)$ such that $\left(q, q^{\prime}\right) \in E$ if and only if $\delta\left(q, q^{\prime}\right) \neq \emptyset$. Any NFA can be easily transformed into an equivalent EFA, with the same underlying digraph: for each pair of states ( $q, q^{\prime}$ ) one needs to construct a regular expression $a_{1}+\cdots+a_{n}$ such that $\left(q, a_{i}, q^{\prime}\right) \in \delta, a_{i} \in \Sigma \cup\{\epsilon\}, 1 \leq i \leq n$.

Finally, we recall the conversion of an EFA $A$ into a regular expression $\alpha$, using the state elimination algorithm (SEA). In each step, a non-initial and non-final state of the EFA is deleted and the transitions are changed in such way that the new EFA is equivalent to the older one. Formally, let $A=\left(Q, \Sigma, \delta, q_{0}, F\right)$ be a EFA. Then

1. (a) If $q_{0} \in F$ or exists $q \in Q$ such that $\delta\left(q, q_{0}\right) \neq \emptyset$, then add a new state $i$ to $Q$, define $\delta\left(i, q_{0}\right)=\epsilon$ and $i$ is the new initial state.
(b) If $|F|>1$, then add a new state $f$ and transition $\delta(q, f)=\epsilon$, for all $q \in F$. The set of final states becomes $\{f\}$.
Without lost of generality, let $A^{\prime}=\left(Q^{\prime}, \Sigma, \delta^{\prime}, i,\{f\}\right)$ denote the new EFA. We denote by $\alpha_{q q^{\prime}}$ the regular expression $\delta\left(q, q^{\prime}\right)$.
2. If $Q^{\prime}=\{i, f\}$, then the resulting regular expression is $\alpha_{i f} \alpha_{f f}^{\star}$, and the algorithm terminates. Otherwise continue to 3 .
3. Choose $q \in Q^{\prime} \backslash\{i, f\}$. Eliminate $q$ from $A^{\prime}$, considering $Q^{\prime}-\{q\}$ the new set of states, and for each $q_{1}, q_{2} \in Q^{\prime}-\{q\}$,

$$
\delta^{\prime}\left(q_{1}, q_{2}\right)=\alpha_{q_{1} q_{2}}+\alpha_{q_{1} q} \alpha_{q q}^{\star} \alpha_{q q_{2}},
$$

Continue to 2 .
Let us observe that, in each step, if we have $q(k ; l)$, the contribution of $q$ for the size of the final regular expression can be measured by

$$
\begin{equation*}
(k-1) \sum_{i=1}^{k}\left|\alpha_{q_{i} q}\right|+(l-1) \sum_{j=1}^{l}\left|\alpha_{q q_{j}}\right|+(k l-1)\left|\alpha_{q q}\right| . \tag{1}
\end{equation*}
$$

This contribution is 0 if $q(1 ; 1)$. To illustrate, this dependence from the order of state elimination in the resulting regular expression, consider the following automaton:

If the order of state removal is $q_{2}, q_{1}, q_{4}$ and $q_{3}$ we obtain the regular expression $a+(b+$ $a a)\left(b a+a(b+a(b+a a))^{*}(b+a a a)\right.$ with 16 alphabetic symbols. If order is $q_{3}, q_{4}, q_{2}$ and $q_{1}$, the resulting expression is $\left.b a(b a)^{*} a+\left(a+b b+b a(b a)^{*} b b\right)\left(a b+a a(b a)^{*} b b\right)^{*} a a(b a)^{*} a\right)^{*}(a+$ $\left.b b+b a(b a)^{*} b b\right)\left(a b+a a(b a)^{*} b b\right)^{*}$ with 44 alphabetic symbols. In each step, we could try to simplify the regular expression obtained, but our goal is try to discover a state order that leads to shorter regular expressions. One of the advantage of this approach is to avoid the generation of bigger intermediate regular expressions.

## 3 UDR Automata

In this section, we will consider only useful acyclic automata with one final state. The underlying digraphs of these automata are called in the literature acyclic st-digraphs [BJG01]. In an acyclic $s t$-digraph there exists only a vertex of indegree 0 (denoted by $s$ ), only a vertex of outdegree 0 (denoted by $t$ ), and each vertice occurs in some path from $s$ to $t$. In an acyclic automaton, the vertices $s$ and $t$ correspond to the initial and final state, respectively.

We are going to characterise a class of automata, using the notion of digraph homeomorphism. Two digraphs are homeomorphic if both can be obtained from the same digraph by a sequence of subdivisions of arcs [Har69, BJG01].

Let consider the digraph ${ }^{1}$

$$
\mathrm{R}^{\rightarrow}=\left(\left\{q_{1}, q_{2}, q_{3}, q_{4}\right\},\left\{\left(q_{1}, q_{2}\right),\left(q_{1}, q_{3}\right),\left(q_{2}, q_{3}\right),\left(q_{2}, q_{4}\right),\left(q_{3}, q_{4}\right)\right\}\right),
$$

represented in Figure 1.

Figure 1: Digraph $\mathrm{R}^{\rightarrow}$

Definition 1. A useful acyclic NFA with one final state is UDR if its underlying digraph does not contain a subgraph homeomorphic to $\mathrm{R} \rightarrow$. We say that the underlying digraph is a UDR digraph.

The digraph in Figure 2, is not UDR, because its underlying digraph contains a subgraph homeomorphic to $\mathrm{R} \rightarrow$, namely, the one obtained by excluding the vertex $q_{3}$ and the arcs $\left(q_{4}, q_{6}\right)$, and ( $q_{5}, q_{10}$ ) (with dashed lines, in the figure). On the other hand, the digraph in Figure 3 is UDR. The automaton presented in the introduction is obviously not UDR.

The name UDR is an acronym of Unique for the Distributivity Rule. If an automaton is not UDR, there are at least two states (with outdegree or indegree greater than 1) such that the order chosen to eliminate them leads to two different regular expressions, one that results from the application of a distributivity rule to the other. In general, one of the choices will lead to a shorter expression, but is not easy to determine which. In the next section, we show that this is not the case if the automaton is UDR. In a UDR automaton, in each step we can choose to eliminate a state $q(1 ; 1)$.

Proposition 1. Any acyclic NFA is equivalent to a UDR automaton.

[^0]

Figure 2: A non-UDRdigraph

Figure 3: A UDRdigraph

Proof. Every acyclic NFA $A=\left(Q, \Sigma, q_{0}, F\right)$ is equivalent to a regular expression in disjunctive normal form, i.e., $\alpha_{1}+\cdots+\alpha_{n}$ where $\alpha_{l}$ is $\epsilon$ or a concatenation of symbols $a_{l j} \in \Sigma$, $\alpha_{l}=a_{l 1} \cdots a_{l k_{l}}, 1 \leq l \leq n$. From this r.e. we can construct a NFA $A^{\prime}=(\{i\} \cup\{f\} \cup$ $\left.\cup_{1 \leq l \leq n} Q_{l}, \Sigma, i,\{f\}\right)$ where $Q_{l}=\left\{q_{l 1}, \ldots, q_{l k_{l}}\right\}, 1 \leq l \leq n$, and such that $\delta^{\prime}\left(i, a_{l 1}\right)=\left\{q_{l 1}\right\}$, $\delta^{\prime}\left(q_{l j}, a_{l j+1}\right)=\left\{q_{l j+1}\right\}$, for $2 \leq j \leq k_{l-1}$, and $\delta^{\prime}\left(q_{l k_{l}}, \epsilon\right)=\{f\}$. The automaton $A^{\prime}$ is trivially UDR.

An interesting open problem is how to obtain from any acyclic NFA a UDR automaton with a minimal number of transitions (size).

## 4 The Characterisation Theorem

Without loss of generality, we can just consider UDR digraphs (instead of automata), $D=$ $(Q, E, i, f)$, where $i$ denotes the initial vertex and $f$ denotes the final vertex. It is obvious that,

Lemma 1. A st-digraph subgraph of a UDR digraph is a UDR digraph.
Lemma 2. Let $D=(Q, E, i, f)$ be a UDR digraph. Let $i(0 ; k), f(0 ; m)$, and $k, m>1$. Suppose that $u$ and $u^{\prime}$ are two distinct vertices adjacent from $i$, and $v$ and $v^{\prime}$ are two distinct vertices adjacent to $f$. If there are two disjoint paths $i u-v f$ and $i u^{\prime}-v^{\prime} f$ then there cannot exist a path $i u-v^{\prime} f$ nor a path $i u^{\prime}-v f$.

Proof. Suppose that exists a path $i u-v^{\prime} f$, partially in dashed line in the picture below:

It is obvious that there will be a subgraph of $D$ homeomorphic to $\mathrm{R} \rightarrow$. This subgraph will contain the vertices $\left\{i, u, q^{\prime}, f\right\}$ (corresponding to the vertices of $\mathrm{R} \rightarrow$ ), where $q^{\prime}$ is the first vertex common to the path $i u-v^{\prime} f$ and to the path $i u^{\prime}-v^{\prime} f$ (at least $v^{\prime}$ or $u^{\prime}$ ). The proof is analogous if there exists a path $i u^{\prime}-v f$.

If $i(0 ; k)$ and $k>1$, let $U$ be the set of the vertices adjacent from $i$. For $u \in U$, let

$$
X_{u}=\{u\} \cup\{q \mid q \in Q \backslash\{f\} \text { and there exists a path } u-q\}
$$

Consider the binary relation $\downarrow$ in $U \times U$, such that $u \downarrow u^{\prime}$ if and only if $X_{u} \cup X_{u^{\prime}} \neq \emptyset$.

Lemma 3. If $D$ is a UDR digraph, the relation $\downarrow$ is an equivalence relation on $U$.
Proof. The reflexivity and the symmetry are trivial, we only need to prove the transitivity. Let $u_{1}, u_{2}, u_{3} \in U$ and $u_{1} \downarrow u_{2}$ and $u_{2} \downarrow u_{3}$. Then there exist $q_{1} \in X_{u_{1}} \cup X_{u_{2}}$ and $q_{2} \in$ $X_{u_{2}} \cup X_{u_{3}}$. If $q_{1}=q_{2}$ then $u_{1} \downarrow u_{3}$. Suppose that $q_{1} \neq q_{2}$ and that there is no path $q_{1}-q_{2}$ nor $q_{2}-q_{1}$. Then, we will have the following diagram:

The vertices $\left\{i, u_{2}, q_{1}, f\right\}$ define a subgraph homeomorphic to $\mathrm{R} \rightarrow$, which contradicts the fact that $D$ is UDR.

Lemma 4. Let $D=(Q, E, i, f)$ be a UDR digraph. Let $i(0 ; k), f(0 ; m)$, and $k, m>1$. Let $U$ and $X_{u}$, for $u \in U$ be as above. If $[u]$ is an equivalence class of the relation $\downarrow$ with more than one element, then there exists $q \in Q \backslash\{f\}$ such that:

1. $q \in \cap_{u^{\prime} \in[u]} X_{u^{\prime}}$
2. For all $q^{\prime} \in \cup_{u^{\prime} \in[u]} X_{u^{\prime}}$, every path $i-q^{\prime}-f$ contains $q$.

Proof. The existence of $q$, satisfying 1 is a directed consequence of the argument given in proof of the transitivity of $\downarrow$. If condition 2 does not hold, then the digraph $D$ will have a subgraph homeomorphic to $\mathrm{R}^{\rightarrow}$.

Now we can characterise the essential propriety of a UDR digraph.
Theorem 1. Let $D=(Q, E, i, f)$ be a UDR digraph and $|Q|>2$. Then $D$ has at least $a$ vertex $q$ such that $q(1 ; 1)$.

Proof. The proof is by induction on the number of vertices of the digraph, $|Q|=n$. If $n=3$, it is trivially true. The UDR digraphs with 4 vertices are enumerated in Figure 4, and it is easy to see that all of them have one vertex $q$ such that $q(1 ; 1)$. Assume that the theorem

Figure 4: UDR digraphs with 4 vertices
holds for UDR digraphs with less than $n>4$ vertices. We want to show that the same is true for a $D=(Q, E, i, F)$ with $|Q|=n$. If $i(0 ; 1)$, let $u \in Q \backslash\{f\}$ be the vertex adjacent from $i$.

Then the digraph $D^{\prime}=(Q \backslash\{i\}, E \backslash\{(i, u)\}, u, f)$ is a UDR digraph with $n-1$ vertices, and by induction hypothesis it has a vertex $q$ such that $q(1 ; 1)$. An analogous argument can be given if $f(1 ; 0)$. Let us suppose that $i\left(0 ; k_{i}\right)$ and $f\left(k_{f} ; 0\right)$, with $k_{i}, k_{f}>1$. As we are seeking for an intermediate vertex, we can ignore the $\operatorname{arc}(i, f) \in E$, if it exists. Let $U, X_{u}$ and $\downarrow$ be as defined above. For every $u \in U$, we have one of the following cases:

1. The class $[u]$ has an unique element. Let $D^{\prime}=\left(X_{u} \cup\{f\}, E^{\prime}, u, f\right)$, where $E^{\prime}$ has all the arcs of $D$ with vertices in $X_{u} \cup\{f\}$. Then by Lemma $1, D^{\prime}$ is a UDR digraph and has less than $n$ vertices. If $\left|X_{u} \cup\{f\}\right|=2$, then $u(1 ; 1)$ in $D$. Otherwise, by induction hypothesis, $D^{\prime}$ has a vertex $q^{\prime}$ such that $q^{\prime}(1 ; 1)$, and, in $D$ we have also $q^{\prime}(1 ; 1)$ (by Lemma 2).
2. The class $[u]$ has more than one element. Consider $q$ as defined in Lemma 4. Let $D^{\prime}=\left(\cup_{u^{\prime} \in[u]} X_{u^{\prime}}, E^{\prime}, i, q\right)$, where $E^{\prime}$ has all the arcs of $D$ with vertices in $\cup_{u^{\prime} \in[u]} X_{u^{\prime}}$. Then by Lemma $4, D^{\prime}$ is a UDR digraph and has less than $n$ vertices. By induction hypothesis, it has a vertex $q^{\prime}$ such that $q^{\prime}(1 ; 1)$, and, in $D$ we have also $q^{\prime}(1 ; 1)$.

## 5 Computing Regular Expressions from UDR Automata

Theorem 2. Let $A=(Q, \Sigma, i, \delta, f)$ be a useful acyclic $N F A$ with an unique final state. We can obtain a regular expression equivalent to $A$ using the state elimination algorithm (SEA) in such way that in each step we remove a state $q$ with $q(1 ; 1)$ if and only if $A$ is UDR.

Proof. Suppose that $A$ is UDR. If $Q=\{i, f\}$ then there is nothing to be proven. Otherwise, by Theorem 1, we can choose a state $q$ to eliminate such that $q(1 ; 1)$. The resulting EFA $A^{\prime}$ is UDR, since with that elimination step no automaton state increases its indegree nor its outdegree (at most the adjacent state to $q$, decreases its outdegree by one, and the adjacent state from $q$ decreases its indegree by one).

If we apply the SEA to a useful acyclic non-UDREFA $A$, then the underlying digraph of $A$ has a subgraph homeomorphic to $\mathrm{R} \rightarrow$. Let $q_{1}, q_{2}, q_{3}$ and $q_{4}$ be the corresponding vertices. All of them have either indegree or outdegree greater than 1 , and all those degrees cannot decrease to 1 unless one of the states is eliminated.

Corollary 1. Given a UDR automaton $A$, it is possible to construct an equivalent regular expression with size linear in the size of $A$.

Proof. In the application of the SEA, in each step if $q$ is the state to remove (and $q(1 ; 1)$ ), then $\exists!q_{1} \exists!q_{2}: \delta^{\prime}\left(q_{1}, q_{2}\right)=\alpha_{q_{1} q_{2}}+\alpha_{q_{1} q} \alpha_{q q_{2}}$ and all the other transitions are not changed. The size of the regular expression obtained is the number of transitions of $A$ with alphabetic symbols (counting its multiplicities).

## 6 An algorithm to decide if a digraph is UDR

Fortune and al. [FHW80] have shown that the problem of determining if an acyclic digraph $D=(V, E)$ has a subgraph homeomorphic to a fixed digraph $P=\left(V^{\prime}, E^{\prime}\right)$ has a polynomial time algorithm $O\left(n^{k+s}\right)$, where $n=|V|, m=|E|, k=\left|E^{\prime}\right|$ and $s=\left|V^{\prime}\right|$. However, to determine if a digraph is UDR, a specialised algorithm can be designed.

Let us suppose that we have already determined that $D=(V, E, i, f)$ is an acyclic stdigraph, with a topological ordering $o$ (this can be achieved in $O(n+m)$ ). For $v \in V$, let $\operatorname{AdjT}(v)$ be a list of vertices adjacent to $v$ and let $\operatorname{AdjF}(v)$ be a list of vertices adjacent from v.

In Figure 6 we present the algorithm in pseudo-code. The vertices of the digraph are going to be traversed in topological order. Each $\operatorname{arc}(u, v) \in E$ is annotated with a list of relevant vertices with outdegree greater than 1 , that precedes $v$ (in a path from i). Those labels are denoted by label ( $u, v$ ) and are implemented with references to other labels. The empty list is denoted by nil and l.v represents the concatenation of $v$ with the list 1 . We use $\leftarrow$ as the standard assignment operator. The semantics of an expression $e_{1}=e_{2}$ is defined by induction on the type of $e_{2}$ :

$$
\begin{array}{llr}
\llbracket e_{1}=v a l \rrbracket & \equiv e_{1} \leftarrow v a l & \text { if } e_{2} \text { is a value val } \\
\llbracket e_{1}=\operatorname{ref}\left(e_{3}\right) \rrbracket & \equiv \llbracket e_{1}=e_{3} \rrbracket \quad \text { if } e_{2} \text { is a reference } \operatorname{ref}\left(e_{3}\right) .
\end{array}
$$

We use other standard list operations as first (first element of the list), last (last element of the list) and butlast (the list without the last element).

The algorithm proceeds as follows. While the visited vertices have indegree less than 2 , the relevant predecessors are collected (lines 19-26). If a vertice v1 has indegree greater than 1 , then either we can "resolve" all the precedent bifurcations or the digraph must be non UDR (lines 4-18). A junction is "resolved" if there are two vertices, v and vi adjacent to v1 with labels that have equal values but which are not references to the same object. In this case, those labels can be unified and if vp is the last element of those labels, outd (vp) is decreased by 1 . When that value is 1 , the vertice vp is no longer relevant an can be deleted from the labels (lines 7-15).

Theorem 3. The algorithm udrp is correct and has time complexity $O\left(n^{2} \log n\right)$.
Proof. (Sketch) If the digraph $D$ is not UDR, it has a subgraph homeomorphic to $\mathrm{R} \rightarrow$. Let $q_{1}, q_{2}, q_{3}$ and $q_{4}$ be the corresponding vertices. The vertice $q_{3}$ has indegree greater than 1. When $q_{3}$ is visited, there are $v, v^{\prime} \in \operatorname{AdjF}\left(q_{3}\right)$ such that $q_{1} \in \operatorname{label}\left(v, q_{3}\right)$ and $q_{1}, q_{2} \in \operatorname{label}\left(v^{\prime}, q_{3}\right)$. Those labels can never refer to the same object, thus the algorithm must return 0 .

Suppose that the algorithm returns 0 . Then there exists $v \in \mathrm{~V}$ such that $v(\mathrm{nf} ; k)$ with $\mathrm{nf}>1$ and there exist $v^{\prime}, v^{\prime \prime} \in \operatorname{AdjF}(v)$ such that $\operatorname{label}\left(v^{\prime}, v\right)$ and label ( $v^{\prime \prime}, v$ ) are diferent. Let $q_{1} \in\left(\operatorname{label}\left(v^{\prime}, v\right) \backslash \operatorname{label}\left(v^{\prime \prime}, v\right)\right)$. The outdegree of $q_{1}$ is greater than 1 (otherwise it was not relevant) and $q_{1} \neq i$. Then there must exist two disjoint paths $i-q_{1}-v_{1}$ and $i-v_{1}$. There exists a path $q_{1}-f$ that does not go through $v_{1}$ and a path $v_{1}-f$ that does not go through $q_{1}$. Thus $D$ has a subgraph homeomorphic to $\mathrm{R} \rightarrow$, defined by $i, q_{1}, v_{1}, q^{\prime}$, where $q^{\prime}$ is a common ancestor of $q_{1}$ and $v_{1}$ (at least $f$ ). Thus the digraph $D$ is not UDR.

Now, we analyse the time complexity. The total cost of executing the lines $23-26$ is $O(m)$. For each $v \in V$, the lines $4-18$ can be, in the worst case, executed $O(n \log n)$ (as the annotations can be sorted only once). The time complexity of udrp is $O\left(n^{2} \log n\right)$.

Proposition 2. If $A$ is UDR, the algorithm udrp can be used to compute an equivalent regular expression with size linear in the size of $A$.

Proof. (Sketch) Let $A=(Q, \Sigma, \delta, i, f)$ be an EFA. In the algorithm udrp we can extend the algorithm annotations of the arcs to contain the automaton's transition labels. For $\left(q, q^{\prime}\right) \in Q$, let label ( $q, q^{\prime}$ ) be the list of vertices as before and let regexp $\left(q, q^{\prime}\right)$ be the

```
udrp {
    for v1 in V ordered topologically do
        nf}\leftarrow|AdjF(v1)
        while nf > 1 do
            max}\leftarrow\operatorname{max}{|label(v,v1)|:v\in\operatorname{AdjF}(\textrm{v}1)
            lmax}\leftarrow{v\in\operatorname{AdjF}(\textrm{v}1):|\operatorname{label}(v,\textrm{v}1)|===\operatorname{max}
            vi}\leftarrow first(lmax
                if v in lmax\{vi} and
                    (ref(label(v,v1)) <> ref(label(vi,v1)) )
                    and (label(v,v1) = = label(vi,v1)) then
                    vp}\leftarrowlast(label(vi,v1)
                    outd(vp) \leftarrow outd(vp) - 1
                    label(v,v1) = ref(label(vi,v1))
                            if outd(vp) = = 1 then
                                    label(v,v1) = butlast(label(v,v1))
                                    nf}\leftarrownf - 1
                                    continue
                            else return 0 % is not UDR
            if v1 = = i then
            lp = nil
            else
                    lp = ref(label(first(AdjF(v1)),v1))
            for v2 in AdjT(v1) do
            if outd(v1) < > 1 then
                    label(v1,v2) \leftarrow lp.v1
            else label(v1,v2) \leftarrow lp
    return 1 % is UDR
}
```

Figure 5: Determining if a digraph is UDR
associated regular expression. Whenever a state $q_{1}(k ; 1)$ is visited and its incident arcs have been resolved (lines 19-26) let rp be the regular expression correspondent to the label lp . Then, in line 26 , we add the instruction

$$
\mathrm{regexp}(\mathrm{v} 1, \mathrm{v} 2) \leftarrow \mathrm{rp} \cdot \mathrm{regexp}(\mathrm{v} 1, \mathrm{v} 2) .
$$

Whenever a junction is resolved (in line 13) we add an instruction

```
regexp(v,v1) = regexp(v,v1) + regexp(vi,v1).
```

And in line 15 , we add another concatenation:

```
\(r \operatorname{eg} \exp (v i, v 1)=r p \cdot r \operatorname{eg} \exp (v i, v 1)\),
```

where rp is the regular expression correspondent to the vertice vp (there must be only one). In the end we obtain the same regular expression of Corollary 1.

## 7 Relationship with other works

There is no much papers in the literature on the characterization of the conversion from NFAs to regular expressions, as was pointed by Ellul and al. [ESwW02]. Giammarresi and al. [GPWZ04] characterised the automata generated by the Thompson method [Tho68] for converting regular expressions to automata. They called the underlying digraphs, Thompson digraphs. By induction on the structure of those digraphs we can prove that

Corollary 2. Every acyclic Thompson digraph is UDR.
In the same way Caron and Ziadi [CZ00] characterised the automata generated by the Glushkov method for transforming regular expressions into finite automata [Yu97]. As these automata may have more than one final state, we cannot directly compare the acyclic Glushkov digraphs and the UDR digraphs. Introducing $\epsilon$-transitions it is possible to obtain an equivalent UDR automata equivalent to an acyclic Glushkov automaton.

## 8 Conclusions

In this work we have characterised a small class of acyclic automata for which it is easy to find short equivalent regular expressions. Determining the exact number of UDR digraphs (and automata) is one of our next goals. Would be interesting to investigate an algorithm to transform any acyclic automaton into a UDRequivalent with minimal size, although in general this problem is NP-complete (it is equivalent to the minimisation of regular expressions without the $\star$ operator). Finally, we hope to extend the UDR notion to acyclic automata with several final states and some restricted classes of cyclic automata.
