Efficient Support for Incomplete and Complete Tables in the YapTab Tabling System

Ricardo Rocha

DCC-FC & LIACC University of Porto, Portugal ricroc@ncc.up.pt

Abstract. Most of the recent proposals in tabling technology were designed as a means to improve some practical deficiencies of current tabling execution models. The discussion we address in this paper was also motivated by practical deficiencies we encountered, in particular, when dealing with incomplete and complete tables. Incomplete tables became a problem when, as a result of a pruning operation, the computational state of a tabled subgoal is removed from the execution stacks before being completed. On the other hand, complete tables became a problem when the system runs out of memory. To handle incomplete tables, we propose an approach that avoids re-computation when the already stored answers are enough to evaluate a repeated call. To handle complete tables, we propose a memory management strategy that automatically recovers space from the tables when the system runs out of memory. To validate our proposals, we have implemented them in the YapTab tabling system as an elegant extension of the original design.

1 Introduction

Resolution strategies based on tabling [1, 2] are able to reduce the search space, avoid looping, and have better termination properties than traditional Prolog models based on SLD resolution [3]. As a result, in the past years several alternative tabling models have been proposed [4–9] and implemented in systems like XSB, Yap, B-Prolog, ALS-Prolog and Mercury.

The basic idea behind tabling is straightforward: programs are evaluated by storing answers for current subgoals in an appropriate data space, called the *table space*. Whenever a repeated call is found, the subgoal's answers are recalled from the table instead of being re-evaluated against the program clauses. The added power of tabling has proved its viability in application areas such as Knowledge Based Systems [10, 11], Program Analysis [12], and Inductive Logic Programming [13].

More recently, the increasing interest in tabling technology led to further developments and proposals that improve some practical deficiencies of current tabling execution models. In [14], Sagonas and Stuckey proposed a mechanism, named *just enough tabling*, that offers the capability to arbitrarily suspend and resume a tabled evaluation without requiring full re-computation. In [15], Saha and Ramakrishnan proposed an incremental evaluation algorithm for maintaining the freshness of tables that avoids recomputing the full set of answers when the program changes upon addition or deletion of facts/rules. In [16], Rocha *et al.* proposed the ability to support dynamic mixed-strategy evaluation of the two most successful tabling scheduling strategies, batched and local scheduling.

All these recent proposals were designed as a means to improve the performance of particular applications in key aspects of tabled evaluation like recomputation and scheduling. The discussion we address in this work was also motivated by our recent attempt [13] of applying tabling to Inductive Logic Programming (ILP). ILP applications are very interesting for tabling because they have huge search spaces and do a lot of re-computation. Moreover, we found that they are an excellent case study to improve some practical deficiencies of current tabling execution models. In particular, in this paper we focus on the table space and how to efficiently handle incomplete and complete tables.

A table is said to be *complete* when its set of stored answers represent all the conclusions that can be inferred from the set of facts and rules in the program for the subgoal call associated with the table. Otherwise, it is said to be *incomplete*. A table for a tabled subgoal is thus marked as complete when, during evaluation, it is determined that all possible resolutions for the subgoal have been made and, therefore, no more answers can be found.

Incomplete tables became a problem when, as a result of a pruning operation, the computational state of a tabled subgoal is removed from the execution stacks before being completed. We may have found several answers but not the complete set. Thus, when a repeated call appears, we cannot simply load answers from an incomplete table, because we may loose part of the computation. The usual approach implemented in most tabling systems is to throw away the already found answers and restart the evaluation from the beginning when a repeated call appears. In this paper, we propose a more aggressive approach and, by default, we keep incomplete tables for pruned subgoals. Then, later, when a repeated call appears, we start by consuming the available answers from the incomplete table, and only if we exhaust all such answers, we restart the evaluation from the beginning. The idea is to avoid any re-computation when the already stored answers are enough to evaluate a repeated call.

On the other hand, complete tables can also be a problem, but when the system runs out of memory space. For such cases we need to compromise efficiency and throw away some of the tables in order to recover space and let the computation continue. Memory handling is a serious problem when we use tabling for applications that store large answers and/or a huge number of answers. The common control implemented in most tabling systems is to have a set of tabling primitives that the programmer can use to dynamically abolish some of the tables. In this paper, we propose a more robust approach, a memory management strategy, based on a *least recently used* algorithm, that automatically recovers space from the tables when the system runs out of memory.

To validate our proposals, we have implemented them in the YapTab tabling system as an elegant extension of the original design [5]. To the best of our knowl-

edge, YapTab is the first tabling system that implements support for incomplete and complete tables as discussed above. Results using the April ILP system [17] showed very substantial performance gains and a substantial increase of the size of the problems that can be solved by combining ILP with tabling. Despite the fact that we use ILP as the motivation for this work, the problems, proposals and results that we discuss next are not restricted to ILP applications and can be generalised and applied to any other application.

The remainder of the paper is organized as follows. First, we briefly introduce some background concepts and discuss the motivation for our work. Next, we present our proposals and describe the issues involved in providing engine support for integrating them in the YapTab tabling system. We then present some experimental results and outline some conclusions.

2 Background and Motivation

To discuss the motivation for our work, we start by introducing some basic concepts about tabling and ILP and then we address the practical deficiencies encountered when combining them.

2.1 Basic Tabling Definitions

Tabling is about storing answers for subgoals so that they can be reused when a repeated call appears. The nodes in a tabled evaluation are classified as either: *generator nodes*, corresponding to first calls to tabled subgoals; *consumer nodes*, corresponding to repeated calls to tabled subgoals; or *interior nodes*, corresponding to non-tabled subgoals. Tabling based models have four main types of operations for definite programs:

- 1. The *tabled subgoal call* operation is a call to a tabled subgoal. It checks if the subgoal is in the table. If so, it allocates a consumer node and starts consuming the available answers. If not, it adds a new entry to the table, and allocates a new generator node.
- 2. The *new answer* operation verifies whether a newly found answer is already in the table, and if not, inserts the answer. Otherwise, the operation fails.
- 3. The answer resolution operation verifies whether extra answers are available for a particular consumer node and, if so, consumes the next one. If no unconsumed answers are available, it *suspends* the current computation and schedules a backtracking node to continue the execution.
- 4. The *completion* operation determines whether a tabled subgoal is *completely* evaluated. It executes when backtracking to a generator node and all of its clauses have been tried. If the subgoal is completely evaluated, the operation marks the corresponding table entry as complete and reclaims stack space. Otherwise, control moves to a consumer with unconsumed answers.

We could delay completion until the very end of the execution. Unfortunately, doing so would also mean that we could only recover space for consumers (suspended subgoals) at the very end of the execution. Instead we shall try to achieve *incremental completion* [18] to detect whether a generator node has been fully exploited and, if so, to recover space for all its consumers. Moreover, if we call a repeated subgoal that is already completed, then we can avoid consumer node allocation and perform instead what is called a *completed table optimization* [19]. This optimization allocates a node, similar to an interior node, that will consume the set of found answers executing compiled code directly from the table data structures associated with the completed subgoal.

2.2 Inductive Logic Programming

The fundamental goal of an ILP system is to find a consistent and complete theory (logic program), from a set of examples and prior knowledge, the *background knowledge*, that explains all given positive examples, while being consistent with the given negative examples. Since it is not usually obvious which set of hypotheses should be picked as the theory, an ILP system must traverse the *hypotheses space* searching for a set of hypotheses (clauses) with the desired properties.

Computing the coverage of a hypothesis requires, in general, running positives and negatives examples against the clause. For instance, to evaluate if the hypothesis 'theory(X):- a1(X), a2(X,Y).' covers the example theory(p1), the system executes the goal once(a1(p1), a2(p1,Y)). The once/1 predicate is a primitive that prunes over the search space preventing the unnecessary search for further answers. It is defined in Prolog as 'once(Goal):- call(Goal),!.'. Note that the ILP system is only interested in evaluating the coverage of the hypothesis, and not in finding answers for the goal.

Now assume that the previous hypothesis obtains a *good coverage*, that is, the number of positive examples covered by it is high and the number of negative example is low. Then, it is quite possible that the system will use it to generate more specific hypotheses such as 'theory(X):- a1(X),a2(X,Y),a3(Y).'. If the same example, theory(p1), is then evaluated against this new hypothesis, goal once(a1(p1),a2(p1,Y),a3(Y)), part of the computation will be repeated. For data-sets with a large number of examples, we can arbitrarily do a lot of recomputation. Tabling technology is thus an excellent candidate to significantly reduce the execution time for these kind of problems.

2.3 Tabling and Inductive Logic Programming

Consider now that we declare predicate a2/2 as tabled. Coverage computation with tabled evaluation works fine when examples are not covered by hypotheses. In such cases, all the tabled subgoals in a clause are completed. For instance, when evaluating the goal once(a1(p1),a2(p1,Y),a3(Y)), if the subgoal a3(Y) never succeeds then, by backtracking, a2(p1,Y) will be completely evaluated. On the other hand, tabled evaluation can be a problem when examples are successfully covered by hypotheses. For example, if once(a1(p1),a2(p1,Y),a3(Y)) eventually succeeds, then the once/1 primitive will reclaim space by pruning the goal at hand. However, as a2(p1,Y) may still succeed with other answers for Y, its table entry cannot be marked as complete. Thus, when a repeated call to a2(p1,Y) appears, we cannot simply load answers from its incomplete table, because we may loose part of the computation. A question then arises: how can we make tabling worthwhile in an environment that potentially generates so many incomplete tables?

In previous work [13], we first studied this problem by taking advantage of YapTab's functionality that allows it to combine different scheduling strategies within the same evaluation [16]. Our results showed that best performance can be achieved when we evaluate some subgoals using *batched scheduling* and others using *local scheduling*. Batched scheduling is the default strategy, it schedules the program clauses in a depth-first manner as does the WAM. This strategy favors forward execution, when new answers are found the evaluation automatically propagates the answer to solve the goal at hand. Local scheduling is an alternative strategy that tries to *force* completion before returning answers. The key idea is that whenever new answers are found, they are added to the table space, as usual, but execution fails. Answers are only returned when all program clauses for the subgoal at hand were resolved.

At first, local scheduling seems more attractive because it avoids the pruning problem mentioned above. When the once/1 primitive prunes the search space, the tables are already completed. On the other hand, if the cost of fully generating the complete set of answers is very expensive, then the ILP system may not always benefit from it. It can happen that, after completing a subgoal, the subgoal is not called again or when called it succeeds just by using the initial answers, thus, making it useless to compute beforehand the full set of answers. Another major problem with mixed-strategy evaluation, is that, from the programmer's point of view, it is very difficult to define beforehand the subgoals to table using one or another strategy. The approach we propose in this work can be seen as a compromise between the efficiency of batched scheduling and the effectiveness of local scheduling. We want to favor forward execution in order to quickly succeed with the coverage evaluation of the hypotheses, but we also want to be able to reuse the already found answers in order to avoid re-computation.

When applying tabling to ILP, we can also explore the fact that an important characteristic of ILP systems is that they generate candidate hypotheses which have many similarities among them. Usually, these similarities tend to correspond to common *prefixes* (conjunction of subgoals) among the candidate hypotheses. Thus, if we are able to table these conjunction of subgoals, we only need to compute them once. This strategy can be recursively applied as the system generates more specific hypotheses. This idea is similar to the *query packs* technique proposed by Blockeel *et al.* [20].

However, to recursively table conjunction of subgoals, we need to store a large number of tables, and thus, we may increase the table memory usage arbitrarily and quickly run out of memory [13]. Therefore, at some point, we need to compromise efficiency and throw away some of the tables in order to recover space and let the computation continue. A first approach is to let the programmer dynamically control the deletion of the tables. However, this can be hard

to implement and difficult to decide what are the potentially useless tables that should be deleted. In order to allow useful deletion without compromising efficiency, in this work, we propose a more robust approach, a memory management strategy based on a *least recently used* replacement algorithm that automatically recovers space from the tables when the system runs out of memory.

We next describe how we extended the YapTab tabling system to provide engine support for handling incomplete and complete tables as discussed above.

3 Handling Incomplete Tables

This section describes our proposal to handle incomplete tables. The main goal of our proposal is to avoid re-computation when the answers in an incomplete table are enough to evaluate a repeated call. To support that, we thus keep incomplete tables for pruned subgoals. Then, when a repeated call to a pruned subgoal appears, we start by consuming the available answers from its incomplete table, and only if we exhaust all such answers, we restart the evaluation from the beginning. Later, if the subgoal is pruned again, then the same process is repeated until eventually the subgoal is completely evaluated. We next describe how we extended the YapTab tabling system to support incomplete tables.

3.1 Implementation Details

In YapTab, tables are implemented using *tries* as proposed in [19]. An important data structure in the table space is the *subgoal frame*. For each different tabled subgoal call, a different subgoal frame is used to store information about the subgoal. In particular, part of that information includes a pointer to where answers are stored, the SgFr_answers field, and a flag indicating the state of the subgoal, the SgFr_state field (see Fig. 1 for details).

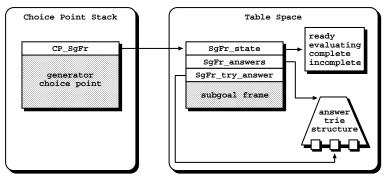

Fig. 1. Generator choice points and subgoal frames in YapTab

During evaluation, a subgoal frame can be in one of the following states: *ready*, i.e., without a corresponding generator in the choice point stack; *evaluating*, i.e., with a generator being evaluated; or *complete*, i.e., with the generator

no longer present but with the subgoal fully evaluated. At the engine level, generator nodes are implemented as WAM choice points extended with two extra fields. One of these fields, the CP_SgFr field, points to the associated subgoal frame in the table space.

To support incomplete tables, we have introduced two minor changes to the subgoal frame data structure. First, a new *incomplete* state, marks the subgoals whose corresponding generators were pruned from the execution stacks. Second, when we are consuming answers from an incomplete table as a result of a repeated call to a previously pruned subgoal, a new SgFr_try_answer field marks the currently loaded answer (similarly to what consumer nodes have). As an optimization, if a subgoal has no answers when its generator is pruned, then we can avoid marking its table as incomplete. Instead, we can mark it as ready and, when a repeated call appears, proceed as if it was the first call.

Handling incomplete tables also required minor changes to the tabled subgoal call operation. Figure 2 shows how we extended the tabled_subgoal_call() instruction to deal with incomplete tables.

```
tabled_subgoal_call(subgoal SG) {
  sg_fr = search_table_space(SG)
                                     // sg_fr is the subgoal frame for SG
  if (SgFr_state(sg_fr) == ready) {
    gen_cp = store_generator_node(sg_fr)
    SgFr_state(sg_fr) = evaluating
    CP_AP(gen_cp) = failure_continuation_instruction()
                                                          // second clause
    goto next_instruction()
 } else if (SgFr_state(sg_fr) == evaluating) {
    cons_cp = store_consumer_node(sg_fr)
    goto answer_resolution(cons_cp)
                                                // start consuming answers
 } else if (SgFr_state(sg_fr) == complete) {
                                    // execute compiled code from the trie
    goto SgFr_answers(sg_fr)
 } else if (SgFr_state(sg_fr) == incomplete) {
                                                      // new block of code
    gen_cp = store_generator_node(sg_fr)
    SgFr_state(sg_fr) = evaluating
    first = get_first_answer(sg_fr)
    load_answer_from_trie(first)
    SgFr_try_answer(sg_fr) = first
                                         // mark the current loaded answer
    CP_AP(gen_cp) = table_try_answer
                                                        // new instruction
    goto continuation_instruction()
 }
}
                Fig. 2. Pseudo-code for tabled_subgoal_call()
```

The new block of code that deals with incomplete tables is similar to the block that deals with first calls to tabled subgoals (ready state flag). It also stores a generator node, but instead of using the program clauses to evaluate the subgoal call, as usual, it starts by loading the first available answer from the incomplete table. The subgoal's SgFr_try_answer field is made to point to this first answer. A second difference is that the failure continuation pointer of the generator choice point, the CP_AP field, is now updated to a special table_try_answer instruction.

The table_try_answer instruction implements a variant of the answer resolution operation (see section 2.1). Figure 3 shows the pseudo-code for it. Initially, the table_try_answer instruction checks if there are more answers to be consumed, and if so, it loads the next one and updates the SgFr_try_answer field. When this is not the case, all available answers have been already consumed. Thus, we need to restart the computation from the beginning. The program counter is made to point to the first clause corresponding to the subgoal call at hand and the failure continuation pointer of the generator is updated to the second clause. At this point, the evaluation is in the same computational state as if we had executed a first call to the tabled subgoal call operation. The difference is that the table space for our subgoal already stores some answers.

```
table_try_answer(generator GEN) {
  sg_fr = CP_SgFr(GEN)
 last = SgFr_try_answer(sg_fr)
                                             // get the last loaded answer
 next = get_next_answer(last)
                                                // answers still available
 if (next) {
    load_answer_from_trie(next)
    SgFr_try_answer(sg_fr) = next
                                       // update the current loaded answer
    goto continuation_instruction()
 } else {
                          // restart the evaluation from the first clause
    PREG = get_compiled_code(sg_fr)
                                            // PREG is the program counter
    CP_AP(GEN) = failure_continuation_instruction()
                                                          // second clause
    goto next_instruction()
 }
}
```

Fig. 3. Pseudo-code for table_try_answer()

We should remark that the use of generator nodes to implement the calls to incomplete tables is strictly necessary to maintain unalterable all the remaining data structures and algorithms of the tabling engine. Note that, at the engine level, these calls are again the first representation of the subgoal in the execution stacks because the previous representation has been pruned.

3.2 Discussion

Let us consider again the previous ILP example and the evaluation of the goal once(a1(p1),a2(p1,Y),a3(Y)) with predicate a2/2 declared as tabled. Consider also that, after a long computation for a2(p1,Y), we found three answers: Y=y1, Y=y2, and Y=y3, and that a3(Y) only succeeds for Y=y3. Primitive once/1 then prunes the goal at hand and a2(p1,Y) is marked as incomplete. Now assume that, later, the ILP system calls again a2(p1,Y) when evaluating a different goal, for example, once(a2(p1,Y),a4(Y)). If a4(Y) succeeds with one of the previously found answers: Y=y1, Y=y2, or Y=y3, then no evaluation will be required for subgoal a2(p1,Y). This is the typical case where we can profit from having incomplete tables. The gain in the execution time is proportional to the cost of evaluating the subgoal from the beginning until generating the proper answer.

On the other hand, if a4(Y) does not succeed with any of the previously found answers, then a2(p1, Y) will be reevaluated as a first call. Therefore, for such a case, we do not take any advantage of having maintained the incomplete table. This means that all the answers stored in the table, Y=y1, Y=y2 and Y=y3, will be generated again. However, as these answers are repeated, a4(Y) will not be called again for them. The evaluation will fail until a non-repeated answer is eventually found. Thus, the computation time required to evaluate once(a2(p1,Y),a4(Y)) for these answers, either with or without the incomplete table, is then equivalent. Therefore, we may not benefit from having maintained the incomplete table, but we do not pay any cost either.

Our proposal is closer to the spirit of the *just enough tabling (JET)* proposal of Sagonas and Stuckey [14]. In a nutshell, the JET proposal offers the capability to arbitrarily suspend and resume a tabled evaluation without requiring any re-computation. The basic idea is that JET copies the execution stacks corresponding to pruned subgoals to an auxiliary area in order to be able to resume them later when a repeated call appears. The authors argue that the cost of JET is linear in the number of choice points which are pruned. However, to the best of our knowledge, no practical implementation of JET was yet been done.

Compared to JET, our approach does not require an auxiliary data space, does not require any complex dependencies to maintain information about pruned subgoals, and does not introduce any overhead in the pruning process. We thus believe that the simplicity of our approach can produce comparable results to JET when applied to real applications like ILP applications.

4 Handling Complete Tables

This section describes our proposal to handle complete tables when the system runs out of memory. We propose a memory management strategy that automatically recovers space from the least recently used tables. Note that this proposal is completely orthogonal to the previous one, that is, we can support both independently but we can also support both simultaneously. In what follows, we will consider the case where YapTab also includes support for incomplete tables as described in the previous section. Therefore and despite the fact that here we are focusing the case of complete tables, we will include in the spirit of our proposal the case of incomplete tables too.

4.1 Implementation Details

In YapTab, each subgoal call is represented by a different subgoal frame in the table space. Besides this representation, a subgoal can also be represented in the execution stacks. First calls to tabled subgoals or calls to pruned subgoals are represented by generator nodes; repeated calls to tabled subgoals are represented by consumer nodes; and calls to completed subgoals are represented by interior nodes that execute compiled code directly from the answer trie structure associated with the completed subgoal. A subgoal is said to be *active* if it is represented in the execution stacks. Otherwise, it is said to be *inactive*. Inactive subgoals are thus only represented in the table space.

A subgoal can also be in one of the following states: ready, evaluating, complete or incomplete. The ready and incomplete states correspond to situations where the subgoal is inactive, while the evaluating state corresponds to a situation where the subgoal is active. The complete state is a special case because it can correspond to both active and inactive situations. In order to be able to distinguish these two situations, we introduced a new state named *complete-active*. We use the complete-active state to mark the completed subgoals that are also active in the execution stacks, while the previous complete state is used to mark the completed subgoals that are only represented in the table space. With this simple extension, we can now use the SgFr_state field of the subgoal frames to decide if a subgoal is currently active or inactive.

Knowing what subgoals are active or inactive is important when the system runs out of memory. Obviously, active subgoals cannot be removed from the table space because otherwise we may loose part of the computation or produce errors. Therefore, when the system runs out of memory, we should try to recover space from the inactive subgoals. Figure 4 shows how we extended the YapTab system to handle inactive subgoals.

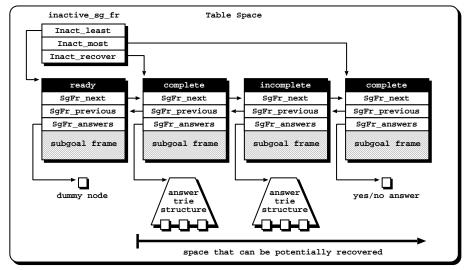

Fig. 4. Handling inactive subgoals in YapTab

Subgoal frames corresponding to inactive subgoals are stored in a double linked list that is accessible by a new data structure named inactive_sg_fr. The Inact_least and Inact_most fields point respectively to the least and most recently inactive subgoal frames. A third field, Inact_recover, points to the next inactive subgoal frame from where space can be potentially recovered. Two subgoal frame fields, SgFr_next and SgFr_previous, link the list. Space from inactive subgoals is recovered as presented next in Fig. 5.

The recover_space() procedure is called when the system fails to allocate memory space for a specific data type, the STR_TYPE argument. It starts from the subgoal frame pointed by the Inact_recover field and then it uses the SgFr_next field to navigate in the list of inactive subgoals until at least a page of memory be recovered for the given data type. YapTab uses a page-based memory allocation

```
recover_space(structure data type STR_TYPE) {
  // STR_TYPE is the data type that we failed to allocate space for
 sg_fr = Inact_recover(inactive_sg_fr)
 do {
    if (sg_fr == NULL)
                                                            // end of list
     return
    if (get_first_answer(sg_fr)) {
                                            // subgoal frame with answers
      free_answer_trie_structure(sg_fr)
                                                          // recover space
                                                  // reset the frame state
     SgFr_state(sg_fr) = ready
    sg_fr = SgFr_next(sg_fr)
 } while (no_space_available_for(STR_TYPE))
                                                   // update recover field
 Inact_recover(inactive_sg_fr) = sg_fr
}
```

Fig. 5. Pseudo-code for recover_space()

scheme where each page only stores data structures of the same type, and thus, to start using a memory page to allocate a different data structure we first need to completely deallocate all the previous data structures from the page.

When recovering space, we only consider the subgoals that store at least one answer (completed subgoals with a yes/no answer are kept unalterable) and for these we only recover space from their answer trie structures. Through experimentation we found that, for a large number of applications, the space required by all the other table data structures is insignificant when compared with the space required by the answer trie structures (usually more than 99% of the total space). Therefore, only sporadically, we are able to recover space from the non-answer related data structures. We thus argue that the potential benefit of recovering space from these structures does not compensate its cost.

During evaluation, an inactive subgoal can be made active again. This occurs when we execute a repeated call to an inactive subgoal. For such cases, we thus need to remove the corresponding subgoal frame from the inactive_sg_fr list. On the other hand, when a subgoal turns inactive, its subgoal frame is inserted in the inactive_sg_fr list as the most recently inactive frame. A subgoal turns inactive when it executes completion, it is pruned or it fails from an interior node that was executing compiled code from the answer trie structure.

This latter case can be complicated because we can have several interior nodes executing compiled code from the same answer trie. Only when the computation fails from the last (older) interior node should the corresponding subgoal be made inactive. To correctly implement that we use the trail stack. The call that first executes code for a completed subgoal changes the subgoal's state to complete-active and stores in the trail stack the reference to the subgoal frame. Further calls for the same subgoal (cases where the subgoal's state is now complete-active) are handled as before. Figure 6 shows how we extended the tabled_subgoal_call() instruction to support this.

When later backtracking occurs, we use the reference in the trail stack to correctly insert the subgoal in the **inactive_sg_fr** list. This use of the trail stack does not introduce any overhead because the YapTab engine already uses the trail to store information beyond the normal variable trailing (to control dynamic predicates, multi-assignment variables and frozen segments).

```
tabled_subgoal_call(subgoal SG) {
  sg_fr = search_table_space(SG)
                                      // sg_fr is the subgoal frame for SG
  if (SgFr_state(sg_fr) == ready) {
    remove_from_inactive_list(sg_fr)
                                                                    // new

4.2 Discussion

A common control implemented in most tabling systems, YapTab included, is to have a set of tabling primitives that the programmer can use to dynamically abolish some of the tables. With our approach, the programmer can still force the deletion of particular tables, but can also rely on the effectiveness of the memory management algorithm to completely avoid the problem of deciding what potentially useless tables should be deleted.

However, we can still increase the table memory space arbitrarily. This can happen if the space required by the set of active subgoals exceeds the available memory space and we are not able to recover any space from the set of inactive subgoals. A possible solution for this problem is to store data externally using, for example, a relational database system. We are already studying how this can be done, that is, how we can partially move tables to database storage and efficiently load them back to the tabling engine. This idea can also be applied to inactive subgoals and, in particular, we can eventually use our memory management algorithm, not to decide what tables to delete but, to decide what tables to move to the database.

5 Experimental Results

To evaluate the impact of our proposals, we ran the April ILP system [17] with YapTab. The environment for our experiments was a Pentium M 1600MHz processor with 1 GByte of main memory and running the Linux kernel 2.6.11.

We first experimented our support to handle incomplete tables and, for that, we used a well-known ILP data-set, the *Mutagenesis* data-set, with two different configurations that we named *Mutagen1* and *Mutagen2*. The main difference between the configurations is that the hypotheses space is searched differently. Table 1 shows the running times, in seconds, for *Mutagen1* and *Mutagen2* using

four different approaches to evaluate the predicates in the background knowledge: (i) without tabling; (ii) using local scheduling; (iii) using batched scheduling; and (iv) using batched scheduling with support for incomplete tables. The running times include the time to run the whole ILP system. During evaluation, *Mutagen1* and *Mutagen2* call respectively 1479 and 1461 different tabled subgoals and, for batched scheduling, both end with 76 incomplete tables.

Tabling Mode	Mutagen1	Mutagen 2
Without tabling	> 1 day	> 1 day
Local scheduling	153.9	143.3
Batched scheduling	278.2	137.9
Batched scheduling with incomplete tables	122.9	117.6

 Table 1. Running times with and without support for incomplete tables

Our results show that, by combining batched scheduling with incomplete tables, we can further speedup the execution for these kind of problems. Batched scheduling allows us to favor forward execution and incomplete tables allows us to avoid re-computation. However, for some subgoals, local scheduling can be better than batched scheduling with incomplete tables. We can benefit from local scheduling when the cost of fully generating the complete set of answers is less than the cost of evaluating the subgoal several times as a result of several pruning operations. Better results are thus still possible if we use YapTab's flexibility that allows to intermix batched with local scheduling within the same evaluation. However, from the programmer point of view, it is very difficult to define the subgoals to table using one or another strategy. We thus argue that our combination of batched scheduling with incomplete tables is an excellent (and perhaps the best) compromise between simplicity and good performance.

We next show how we used another well-known ILP data-set, the *Carcino*genesis data-set, to experiment with our second proposal. From our previous work on tabling conjunctions of subgoals, we selected one of the hypotheses that allocates more memory when computing its coverage against the set of examples in the *Carcinogenesis* data-set. That hypothesis is defined by a prefix that represents the conjunction of 5 tabled subgoals with a total of 20 arguments. Table 2 shows the running times in seconds (or m.o. for memory overflow) for computing its coverage with four different table limit sizes: 576, 384, 192 and 128 MBytes (the table limit size is defined statically when the system starts). In parentheses, it shows the number of executions of the **recover_space()** procedure.

Tabling Mode	576MB	384MB	192MB	$128\mathrm{MB}$
Local scheduling	15.2	15.9(95)	16.9(902)	m.o.(893)
Batched scheduling	11.4	12.6(62)	14.1(523)	m.o.(557)
Batched scheduling with incomplete tables	11.1	12.3(91)	13.9(833)	m.o.(833)

Table 2. Running times with different table limit sizes

Through experimentation, we found that this computation requires a total table space of 576 MBytes if not recovering any space, and a minimum of 160 MBytes if using our recovering mechanism (for Pentium-based architectures,

YapTab allocates memory in segments of 32 MBytes). The results obtained with this particular example show that batched scheduling with incomplete tables is again the best approach. The results also suggest that our recovering mechanism is quite effective in performing its task (for a memory reduction of 66% in table space it introduces an average overhead between 10% and 20% in the execution time). The impact of our proposal in the execution time depends, in general, on the size of the table space and on the specificity of the application being evaluated, i.e., on the number of times it may call subgoals whose tables were previously deleted by the recovering procedure.

6 Conclusions

In this paper, we have discussed some practical deficiencies of current tabling systems when dealing with incomplete and complete tables. Incomplete tables became a problem when, as a result of a pruning operation, the computational state of a tabled subgoal is removed from the execution stacks before being completed. On the other hand, complete tables became a problem when the system runs out of memory space.

To handle incomplete tables, we proposed the ability to avoid re-computation by keeping incomplete tables for pruned subgoals. The typical case where we can profit from having incomplete tables is, thus, when the already stored answers are enough to evaluate repeated calls. When this is not the case, we cannot benefit from it but, on the other hand, we do not pay any cost too. To handle complete tables, we proposed a memory management strategy that automatically recovers space from inactive tables when the system runs out of memory. Both proposals have been implemented in the YapTab tabling system with minor changes to the original design. Preliminaries results using the April ILP system showed very substantial performance gains and a substantial increase of the size of the problems that can be solved by combining ILP with tabling.

Acknowledgments

We are very thankful to Nuno Fonseca for his support with the April ILP System. This work has been partially supported by Myddas (POSC/EIA/59154/2004) and by funds granted to LIACC through the Programa de Financiamento Plurianual, Fundação para a Ciência e Tecnologia and Programa POSC.
